STILLE SURGICAL INSTRUMENTS

The Ohio Chemical & Mfg. Co. announces its appointment as exclusive representative in the United States for the world famous Stille line of stainless steel surgical instruments.

Stille instruments are manufactured by A. B. Stille-Werner Stockholm. The international reputation of Stille reflects the accumulated results of the skill and efforts of master craftsmen during a century of designing and manufacturing precision-made instruments.

The Improved Mueller-Balfour Retractor

Provides a Wider Operating Field—

A Deep Blade Model Is Also Available

*The Beckman Adson
Laminectomy Retractor*

The New Foss Gall Bladder Retractor

A wider operating field for the surgeon is the main advantage of the new construction now adopted as standard for all Mueller-Balfour Abdominal Retractors. The blades have been lengthened from $2\frac{1}{4}$ to a little more than 9 inches, which allow full retraction to spread 12 to 16 inches. (The usual limit is only about $12\frac{1}{2}$ inches.)

CO-30 Improved Balfour Retractor Three blades, solid center blade. Chrome plated. Each **\$16.50**

CO-32 Balfour Retractor Wide model also available with special deep blades for maximum retraction in large or obese patients. Three deep blades. Chrome plated. Each **\$25.00**

The new Foss Gall Bladder Retractor is great in cholecystectomy in which the gall bladder is dissected from above downward. The flat prong blades, about 3 inches wide overall, have a center slot $1\frac{1}{2}$ inches wide and $3\frac{1}{2}$ inches deep. The prongs, which flare outward slightly at the ends, are smoothly rolled. Chrome plated. Each, **\$17.50**

Now hand forged in tailless steel, the Beckman Adson Laminectomy Retractor has long sharp teeth which hold firm in the tissues. The steel arm provides maximum adaptability to the individual case. Self-retaining with rat bite teeth.

BS-260R Beckman-Adson Retractor Each **\$39.50**

As an Aid in the
Prevention of
Asphyxia
in the Hospital...

Kreiselman Resuscitators

An informative 36-page booklet just published gives complete details about Kreiselman Resuscitators. This booklet will be supplied upon request, together with copy of the reprinted article "The Treatment of Asphyxia" by Joseph Kreiselman, M.D., Consultant in Anesthesiology, George Washington University Medical School.

FOR many years Kreiselman Resuscitators have been used by leading hospitals and prominent physicians and have been proved correct in principle, efficient and simple to operate, and durable.

These resuscitators operate on positive pressure principle and with pre-selected pressures ranging from 2 to 25 mm. mercury (On infant models pressures range from 2 to 15 mm. mercury) The model illustrated above is combined resuscitator and heated bassinet thermostatically controlled. The heat is always constant and correct.

Included in the Kreiselman line are machines for adults and infants—heated bassinet models and bassinets with hood tents.

Now Offered with Detachable Blade and Thickness Gauges
Modified Blair-Brown Skin Grafting Knife with Marck's Thickness Determining Attachment

At the suggestion of many users, the new Blair Brown Skin Grafting Knife is now offered with a detachable blade and the Marck's Thickness Determining Attachment is now furnished with a set of four copper plate gauges for accurately regulating the thickness of the desired skin graft from 6 to 56 thousandths of an inch in 2 thousandths inch steps. In use, the gauges are selected for the desired thickness and are then placed between the knife edge and the threaded grip rod as shown in illustration "H" above. The knurled thumb screws at both ends of the Marck's Attachment then are adjusted until the space between the grip rod and knife edge provides a light tension on the gauges.

The detachable blade feature greatly reduces the cost of using the knife since extra blades are inexpensive and make it possible to own the equivalent of five knives at less than the

former cost of two knives. These blades are made of razor steel and when properly stropped by the emery floor method before each operation have been used in twenty or more operations before needing honing. A honing tube, "H," is supplied with each knife to facilitate changing the angle for proper honing. A metal container which will hold seven blades is also included for use in storing and sterilizing the blades.

- B-3967 — Modified Blair Brown Skin Grafting Knife, "B," complete with one blade, Marck's Thickness Determining Attachment and set of four gauges \$18.50
- B-3968 — Modified Blair Brown Skin Grafting Knife, "D" (same as above but without Thickness Determining Attachment) \$8.50
- B-3970 — Blair Brown Knife Blades only each \$2.00

Scanlan Sutures

SAVE TIME

SCANLAN non-bulkable sutures are ready for use direct from the sterile tube. Positive sterility is obtained by high heat sterilization, carefully controlled and verified by thorough bacteriological tests.

With Scanlan Sutures, the surgeon has a wide range of needle types and sizes from which to choose in both yeless (swaged-on) and eye (threaded) types of surgical needles.

Send the coupon for catalog of Scanlan Sutures.

Pierre and Marie Curie, physicists and chemists, whose brilliant work on radioactivity lead to their discovery of polonium and radium, for which they were awarded 1903 Nobel prize in physics.

FORWARD STEPS IN SCIENCE

As the discovery of radium by Pierre and Marie Curie was one of the great forward steps in modern science, so SKLAR's adaptation of Stainless Steel to the highly specialized field of surgical instrument making represents a significant forward step in the practice of surgery.

SKLAR research evolved the alloys best suited to produce Stainless Steel instruments. SKLAR craftsmanship—much of it derived from close association with leading surgeons in the making and designing of fine precision instruments—developed the manufacturing techniques essential to superlative production standards. The resulting instruments are strong, resilient, well balanced and always dependable.

Today J SKLAR MANUFACTURING COMPANY makes the greatest variety of stainless steel instruments ever made by a single manufacturer. SKLAR products are available through accredited surgical supply distributors.

"Ohio" CYCLOPROPANE

To the medical profession, the name Ohio on a cylinder of cyclopropane is doubly significant. "Ohio" not only represents highest purity quality and uniformity but is also a reminder that cyclopropane has gained favorable recognition as a dependable anesthetic through the pioneering and assistance supplied by "Ohio" laboratories and "Ohio" technicians in the development of cyclopropane for anesthesia.

One of the world's leading manufacturers of medical gases and administering equipment "Ohio Chemical" is constantly on the alert always ready to pioneer and to assist in new developments which will provide the medical profession with safe, dependable anesthetics.

The Ohio Chemical & Mfg. Co., General Offices 60 East 43rd St., New York 17 N. —Headquarters Division, Manufacturing—Medical Gas Division, Cleveland—Hospital Supply and Waters Laboratory Division, New York—Scientific-Medical Division, Philadelphia, Pa.—Represented in Canada by Oxygen Company of Canada Limited, and Internationally by Airco Export Corporation.

Ohio Medical Gases include Nitrous Oxide—Ethylene—Cyclopropane—Oxygen—Carbon Dioxide—Oxygen-Carbon Dioxide Mixtures—Helium—Helium-Oxygen Mixtures.

Quality COUNTS, TODAY

MORE THAN EVER, the inherently superior qualities which characterize every surgical instrument bearing the Kny-Scheerer trademark become doubly important to the discriminating surgeon during this period of national emergency.

Technical correctness of design and construction, comparable only to the finest instruments previously imported; precision accuracy; the contribution of meticulously trained craftsmen; functional dependability; the resultant use of superior materials and production methods—all are distinctive features of basic importance. Economically they insure longer periods of satisfactory instrument service. Clinically they aid in the most careful attainment of the surgical objective.

TRAUMATIC ANEURYSM

The Matas Operation—Fifty-Seven Years After

DANIEL C. ELKIN M.D., F.A.C.S. Colonel M.C. A.U.S.

White Sulphur Springs, West Virginia

THE report of the first patient treated by endoaneurysmorrhaphy was made by Dr. Rudolph Matas in the *Philadelphia Medical News* October 27, 1888. In the 57 years which have intervened since that memorable publication no alterations in the technique of the procedure other than minor niceties have been made. Few operations have stood this test of time and none has had a more profound effect upon the surgery of blood vessels.

Dr. Matas has recorded the story of his first operation as follows:

On April 6, 1888, I operated upon a young male Negro for a very large traumatic (multiple gunshot) aneurysm of the brachial artery extending from the armpit to the elbow which opened my eyes to the possibilities of an entirely new method of conservative treatment which was to revolutionize my previous notions of aneurysmal surgery. In this case, the successive ligation of the main artery on the proximal and distal poles of the aneurysm had been followed by relapse and it seemed to me, then, that I had no other alternative but to extirpate the sac. When I exposed the sac and emptied its contents the failure of the ligations to control the circulation was easily explained by the appearance in the bottom of the sac of three large orifices corresponding to the collateral branches which opened into the sac in the segment of the artery included between the ligatures (Fig. 1). It was evident that it was these collateral orifices that fed the sac despite the ligatures that had been placed at each one of its poles.

From the Vascular Surgery Center, Ashford General Hospital, White Sulphur Springs, West Virginia.

I at first intended to secure these collaterals by excising the sac, but the branches of the brachial plexus of nerves were so densely incorporated in its walls that I could not have dissected them out and detached them without serious damage thereby paralyzing the arm. It occurred to me then that the easiest way out of this awkward dilemma was to seal the orifices of all the bleeding collaterals by suturing them as we would an intestinal wound leaving the sac attached and undisturbed in the wound. This procedure was at once put into effect and the hemostasis was so perfect and satisfactory that it seemed to me strange that no one should have thought of so simple an expedient before.

Prior to the introduction of this procedure aneurysms were treated by a variety of methods most of them unsuccessful. Compression by various methods (digital bandaging, instrumental) and the introduction of sclerosing and coagulating agents were employed. Older operative methods included that of Antyllus (fourth century A.D.) which consisted of ligation of the vessel above and below the sac, the evacuation of its contents and the application of an astringent or of packing. Aclis's operation (1710) consisted of ligation of the proximal artery close to the sac. One half century later John Hunter tied the femoral artery in the canal which bears his name for aneurysm of the popliteal artery. It was Hunter's idea to bring clotting and eventual cure of the aneurysm and at the same time preserve a collateral circulation. In this

he was highly successful except for the frequent recurrences which took place through the circulation which he was so anxious to preserve. As has been pointed out by Homan since Hunter's time the preservation of the collateral circulation has become an essential part of every curative procedure. It is upon this theory that the Matas endoaneurysmorrhaphy is based. Later Braxdor and Wardrop independently ligated the artery or one of its principal branches on the distal side of the sac in an attempt to arrest the circulation through it. These procedures were at best a makeshift and were usually performed only when the position of the aneurysm prevented other forms of treatment. In many instances amputations were performed for the relief of pain and in order to prevent an almost certain eventual fatal hemorrhage. All of these methods with the exception of the Matas procedure were frequently followed by infection, hemorrhage, gangrene or failure to cure the condition (Fig 2).

The incidence of multiple injuries in the present war as a result of high explosive shells, grenades and antipersonnel mines has led to the production of a larger number of vascular injuries than in any other conflict. While small fragments are more apt to cause arteriovenous fistulas many produce false aneurysms as well and to many of these the principle of intrasaccular closure is applicable. In cases in which the aneurysm is large and in which its dissection would unquestionably result in damage to surrounding structures such as muscles, nerves and other blood vessels, the Matas operation is certainly the procedure of choice. It is difficult to employ in a small aneurysm or where the lesion is accompanied by nerve damage. Here the passage of sutures may damage neural structures and it is better to carry out neurolysis or nerve suture as a single procedure with excision of the aneurysm. However, the principle of intrasaccular suture may well be applied to those instances of arteriovenous aneurysm in which a large venous sac is present as in Case 8 (Fig 3).

The endoaneurysmorrhaphy of Matas is simple in conception and if the principles of

its application are borne in mind it is extremely easy to carry out. Wherever possible a tourniquet should be applied before the sac is opened but if this is precluded by the position of the aneurysm temporary occlusion of the proximal vessel as shown in Cases 1, 2 and 3 is of aid in performing the operation in a less bloody field. As soon as the sac is opened and its clot is evacuated search should be made for the openings in the artery into the aneurysm. If not readily found, temporary loosening of the tourniquet will disclose their position. Usually one or two figure-of-eight sutures of medium silk are sufficient to close the openings but if any bleeding occurs following removal of the tourniquet these can be re-enforced by the placing of other sutures (Fig 4). Actual obliteration of the sac by sutures is difficult because of its friable nature and any suture is apt to cut through. When bleeding is controlled and the clot including the lamellations, is removed the sac will readily collapse and its walls coalesce with the application of a snug elastic bandage. In some instances, the proximal and distal vessels can be dissected from surrounding structures within the sac and individually ligated (Fig 4). When this is done there is less danger of injuring concomitant veins or neural structures, and the vessels are ligated with more confidence.

One hundred and six instances of false aneurysm have been treated by operation at this hospital in the past 30 months. In 61 the Matas procedure has been employed and in 45 some other type of operation, usually complete excision of a small sac, has been the method used. The location of the lesions treated by intrasaccular suture is shown in Table I.

Results. There have been no deaths in this series, no recurrence and no instance of gangrene. Sympathetic interruption has not been practiced either before or after operation but it is admittedly a valuable adjunct in increasing blood flow in the presence of ischemia. Careful tests for evaluating collateral circulation were routinely carried out before the operation and when it appeared that the circulation was impaired compression of the vessel proximal to the aneurysm was carried out for some

Fig 1 The original photograph and drawing shown in report of Dr. Matas, *Philadelphia Medical Voez*, October 27 1893.

time before operation. In general it was believed that if a period of 3 months had elapsed between injury and operation adequate collateral flow had been established. This feeling has been justified in view of the results.

ILLUSTRATIVE CASES

CASE 1: False aneurysm left gluteal artery due to high explosive shell fragment wound. Incurred February 27 1945. Extraperitoneal temporary occlusion of common iliac artery. Endoaneurysmorrhaphy superior gluteal artery. June 8 1945. Recovery.

This 26 year old soldier received multiple wounds in the region of the left hip from high explosive shell fragments. Bleeding was not profuse. Because of abdominal pain and swelling in his hip region and the presence of an abdominal mass which could be palpated by rectum an operation was performed in England on April 12 1945 at which time the left internal iliac artery was ligated. There was some improvement in his symptoms but in the 30 days prior to admission to Ashford General hospital on June 3 there was increased swelling in the left hip and buttock with severe pain controlled only by morphine. On admission there was a large soft mass over the whole left hip region extending as far medially as the sacrum (Fig 5a). There was a small healed wound in the center of this massive swelling. Directly over the mass a systolic murmur could be heard and the mass pulsed synchronously with the heart beat.

On June 8 1945 operation was performed under continuous spinal anesthesia. The common iliac artery was exposed through an extraperitoneal incision and a ligature was passed around it which was not tied and the vessel was temporarily occluded with an artery clamp. A vertical incision was then made directly over the center of the aneurysm (Fig 5b) and clot measuring 700 cubic centimeters in volume was evacuated. With removal of the clot there was considerable bleeding which was found to come from two openings in the superior gluteal artery about 1.5 centimeters apart. Both openings were closed with two figure-of-eight sutures with complete control of the bleeding. The clamp previously placed on the common iliac artery was then removed which caused some bleeding from the muscles and skin which was easily controlled. Both wounds were then closed in layers with interrupted sutures of silk. His recovery was without event and the pain previously complained of rapidly disappeared.

CASE 2: False aneurysm right femoral artery due to high explosive shell fragment wound incurred July 5 1944. Endoaneurysmorrhaphy. August 13 1944. Recovery.

This 26 year old soldier was struck by high explosive shell fragments on July 5 1944. He received multiple wounds of both legs. While in an evacuation hospital, he had three hemorrhages from wounds of the left leg and on July 17 1944, one was so severe as to require ligation of the left posterior tibial artery and vein. Since the time of the original wounds he had noticed gradual enlargement of the right anterior thigh region which continued to in-

Fig. 2. Diagrammatic Illustration of the types of operation employed for the treatment of aneurysms prior to the introduction of endoaneurysmorrhaphy

crease in size until his transfer to Ashford General Hospital, August 13, 1944. At that time he was complaining of pain in the right thigh. On examination there were numerous small well healed wounds in the left leg. On the upper anterior surface of the right thigh there was a large mass 15 by 30 centimeters. The mass was pulsating and over it a harsh systolic murmur could be heard (Fig. 6a).

Since the mass was steadily increasing in size, an immediate operation was carried out. Through a small transverse incision just below Poupart's ligament, the common femoral artery was identified and temporarily occluded with an artery clamp. An incision 8 inches long was then made along the course of the femoral artery directly over the aneurysm (Fig. 6b). The sac was opened and approximately 1200 cubic centimeters of clot was evacuated. Two openings in the femoral artery were closed with figure-of-eight sutures. The vessel was at the bottom of the sac which was bound by Hunter's canal posteriorly and the sartorius muscle anteriorly (Fig. 6c). The clamp was released from the femoral artery and there was no further bleeding. The deep fascia and skin were closed with interrupted sutures of silk and a tight pressure bandage applied. His recovery was uneventful and the circulation in his foot and toes remained good.

CASE 3 False aneurysm, left superficial femoral artery and false aneurysm left profunda femora

artery upper third due to high explosive shell fragment wounds incurred August 29 1944. Endoaneurysmorrhaphy left femoral artery upper third. Endoaneurysmorrhaphy left profunda femora artery upper third October 13 1944. Recovery

On August 29, 1944 this 32 year old soldier was struck by two shell fragments, both of which entered the anterior surface of the left thigh. The wounds were debrided and closed. About 5 days after injury a swelling developed in the left anterior thigh region which was diagnosed as an aneurysm and he was evacuated to the United States. Shortly after reaching this country swelling began to increase gradually and he was admitted to Ashford General Hospital, October 11 1944. At that time, he was complaining of pain in the leg and thigh. There was a massive spherical swelling on the anterior surface of the left thigh, about 10 centimeters below Poupart's ligament (Fig. 7a). The mass pulsated with each heartbeat but there was no thrill. A distinct systolic bruit could be heard over it.

On October 13 1944 operation was performed under spinal anesthesia. A small transverse incision was made over the femoral artery just below Poupart's ligament and a temporary nonoccluding suture was passed around it. It was then occluded with a bulldog artery clamp. A longitudinal incision 6 inches long was made over the swelling, along the course of the femoral vessels (Fig. 7b).

Fig. 3 Steps generally employed in the transvenous or transmuscular repair of an arteriovenous fistula with preservation of the artery

The sac was opened and a clot about 500 cubic centimeters was evacuated. There was brisk bleeding from an opening in the femoral artery which was easily stopped by pressure with the fingers and was closed with several interrupted sutures of silk. The vessel just proximal and distal to this opening was dissected free from surrounding structures and again ligated.

Following this the thigh still appeared tense and firm and, on this account, the fascia covering the adductor group of muscles was incised and another larger aneurysm disclosed. A clot of approximately 1000 cubic centimeters was evacuated and an opening was found in the profunda femoris artery. This was closed with 4 interrupted sutures of silk. The sac was limited posteriorly by the adductor magnus muscle and laterally by the femur (Fig. 7c). The deep fascia and skin were closed with interrupted sutures of silk, and a snug pressure bandage was applied. In spite of the ligation of the superficial femoral and profunda femoris arteries, circulation in his toes and foot was good at the end of the operation and remained so. The wound healed without difficulty.

CASE 4. False aneurysm right external iliac artery due to bullet wound incurred June 27 1944

Endoneurysmorrhaphy and proximal ligation of the external iliac artery September 16 1944

This officer received a through-and-through 30 caliber bullet wound of the abdomen June 27 1944. The bullet entered the right lower quadrant anteriorly and made its exit just to the right of the 5th lumbar vertebra. Shortly thereafter he was operated upon and several perforations of the small intestine were repaired. His recovery from this operation was prompt except for superficial wound infection which soon healed. He was admitted to Ashford General Hospital August 28, 1944 complaining of pain in the right groin and throbbing in the right lower abdomen.

On examination there was a well healed lower right paramedian scar extending from the umbilicus to Poupart's ligament. Immediately above Poupart's ligament and underlying the scar was a mass approximately 6 centimeters in diameter. The mass was pulsating with each heart beat, and a systolic bruit could be heard over it. There was no thrill. The right dorsalis pedis and posterior tibial pulses could be felt, but both were weak in comparison to the other side. Oscillometric readings were diminished on the right.

Operation was performed September 16 1944. The old scar which had been made for the closure of

Fig. 4. Diagrammatic illustration of endoaneurysmorrhaphy. A, Cross section of artery with false sac. B, Sutures are placed to close the arterial openings within the sac. C, Sutures tied. D, Occasionally the vessel is isolated and ligated. E, Occasionally the sac is obliterated by further sutures.

intestinal perforation was excised. The peritoneum was dissected upward until the artery above the aneurysm could be reached. It was isolated and temporarily occluded with an artery clamp. The artery distal to the aneurysm was treated in a similar manner. The sac was opened and two arterial openings in it were closed with interrupted sutures of silk. On removal of the clamp there was still some bleeding from the proximal opening which could be controlled only by ligation of the artery proximal to the aneurysm. No attempt was made to

remove the sac (Fig. 8). The wound was closed in layers. Circulation in the foot and toes was good at the end of the operation and remained so. The patient's recovery was uneventful and he was returned to duty of a limited nature.

CASE 5. False aneurysm, right axillary artery, due to high explosive shell fragment wound incurred May 10, 1944. Endoaneurysmorrhaphy June 23, 1944. Recovery.

This soldier was wounded on May 1, 1944, by a small shell fragment entered his anterior chest just beneath the right clavicle and made its exit just below the scapula on the right side. Subsequently he developed a hemothorax which necessitated aspiration. At the time of his injury there was considerable bleeding from the wound in the anterior chest, which was controlled by pressure. Immediately following the wound he also noticed complete paralysis of the right upper extremity. About June 1, massage and active motion of the right shoulder was begun and shortly after this he noted the appearance of a swelling in the right axillary and subclavicular region. This swelling gradually increased in size until the time of his admission to Ashford General Hospital on June 16, 1944.

Examination at that time revealed a large firm mass which occupied an area beneath the right clavicle and extended into the axilla (Fig. 9, A). The mass was expansile and a definite systolic bruit

could be heard over it. There was evidence of extensive injury to the nerves of the right arm. Pulsation on the right radial artery was faint.

On June 25 1944, because of a rapid increase in size of the aneurysm, operation was performed. An attempt was made to isolate the subclavian artery above the clavicle but it could not be reached because the clavicle was pushed upward by the aneurysm (Fig 9 b). Since it was believed that the clavicle formed a part of the sac wall it was decided

that it was best not to resect it in order to reach the subclavian artery (Fig 9 c). An incision was therefore made across the axilla and the sac was exposed, opened, and approximately 2000 cubic centimeters of blood and clot were evacuated. Bleeding was profuse but was controlled by finger pressure over two openings in the bottom of the sac. These openings were closed with interrupted sutures of silk. Because of the necrotic appearance of the sac and the large dead space which could not be obliterated a

Fig. 8. Diagrammatic illustration showing operative procedure used in Case 4.

drain was left in the wound for 24 hours. His recovery was uneventful. The hand and fingers have remained warm. Two months later nerve repair of the radial, median, and ulnar nerves was done. At present there is evidence of returning nerve function.

CASE 6 False aneurysm, right brachial artery due to mortar shell fragment wound incurred August 6, 1944. Endoaneurysmorrhaphy right brachial artery lower third December 13, 1944. Recovery.

This 23 year old soldier was wounded by mortar shell fragment on August 6, 1944. The fragment entered the posterior surface of the forearm just below the elbow and caused a compound fracture of the ulna. Bleeding was slight and controlled by a pressure bandage. At the same time he sustained an injury to the median nerve which was partial and from which he gradually recovered. At an evacuation hospital in England the wound was debrided, a plaster splint applied and he was returned to the United States. With the removal of the splint, an aneurysm was discovered just below the bend of the right elbow and for this he was admitted to Ashford General Hospital on December 5, 1944.

On admission he complained of pain and throbbing sensation in his right hand. Examination revealed a partial paralysis of the median nerve which was indicated by weakness of the muscles supplied by that nerve but which was said to be improving. Just distal to the right antecubital space was a fluctuant mass about 5 centimeters in diameter (Fig. 10a). There was no thrill, but a systolic bruit could be heard over it. Skin temperatures of both hands were normal and symmetrical, although the right radial pulse was diminished in comparison with the left.

Fig. 9. Case 3. a. Preoperative photograph. Aneurysm of axillary artery. b. The approximate anatomic position of the aneurysm. c. Cross section showing relative size and position of aneurysm.

On December 13, 1914, operation was done under pentothal sodium anesthesia. A blood pressure cuff was used as a tourniquet on the arm. An incision 5 centimeters in length was made directly over the

aneurysm and the sac uncovered (Fig. 10 b). A laminated clot together with fresh clot was evacuated. At the bottom of the sac the brachial artery was easily located. There were two openings in it 1

centimeter apart. Both were closed with interrupted sutures of silk. When the tourniquet was removed there was no abnormal bleeding. The deep fascia and skin were closed with interrupted sutures of silk. No attempt was made to obliterate the sac other than to apply a snug pressure bandage. Circulation in the hand and fingers was good at the end of the operation and remained so. Function of the median nerve returned without further operation.

CASE 7 False aneurysm left radial artery upper third due to high explosive shell fragment wound incurred October 7 1944. Endoaneurysmorrhaphy June 16 1945 Recovery

This 23 year old soldier was wounded in action October 7 1944. He suffered wounds of both upper extremities, the abdomen, and chest. He was operated upon within a few hours for perforations of the ileum and liver from which he recovered without difficulty. After returning to the United States in May the patient first noticed a pulsating tumor of the left forearm, and for this he was admitted to Ashford General Hospital on June 8 1945. On examination there were noted numerous healed scars of both upper extremities, chest, and abdomen. On the lateral volar aspect of the left forearm there was a circumscribed pulsating tumor about 6 centimeters in diameter. Over this mass a systolic bruit could be heard. The skin temperatures of the fingers of both hands were normal and symmetrical. The left radial pulse was weak. There was no associated nerve injury (Fig. 11, a and b).

On June 16 1945 operation was performed under pentothal sodium anesthesia. An inflated blood pressure cuff was used as a tourniquet on the arm. A longitudinal incision 5 centimeters long was made

Fig. 2, a.

Fig. 2, b.

(Legend on followi g page.)

directly over the tumor mass which was easily uncovered. The sac was opened and some old and freshly organized clot was evacuated. The radial artery which was at the bottom of the sac had been partially divided producing an upper and lower opening each of which was closed with sutures of silk. The tourniquet was then removed and there was a slight oozing which was closed with another suture of silk. No attempt was made to obliterate the sac. The deep fascia and skin were closed with interrupted sutures of silk and a pressure bandage was applied from the fingers to the elbow. The circulation of the fingers was good at the end of the operation and remained so.

CASE 8 Arteriovenous aneurysm, left external carotid artery and internal jugular vein with false venous sac, due to shell fragment wound incurred September 23 1944. Paralysis of left recurrent laryngeal nerve. Ligation and division of right external carotid artery. Ligation and division of left

Fig. 10. Case 6. a, above, Preoperative photograph. Aneurysm of brachial artery b, below Postoperative photograph showing incision.

common carotid artery and internal jugular vein ligation and division of distal arterial branches Endoaneurysmorrhaphy Recovery

This 36 year old soldier was wounded in action by a mortar shell fragment which struck the infra orbital region of his cheek. He was unconscious for approximately 10 days during which time a tracheotomy was performed because of respiratory difficulties. The tracheal tube was removed after 3 weeks. Soon after the injury a mass was noted in the left side of his neck and, on recovery of consciousness, he noticed that the left eyelid drooped and that he was hoarse. He was returned to the United States and admitted to Ashford General Hospital on December 19 1944.

Examination revealed a small wound just below the left eye. Roentgenogram showed a foreign body in the left suprascapular region. There was definite Horner's syndrome on the left and paralysis of the left recurrent laryngeal nerve. In the left side of the

neck extending from the ear almost to the clavicle was a mass of dilated vessels which was easily compressible (Fig 12a).

A harsh continuous bruit accentuated in systole could be heard over the mass and was transmitted to the scalp down the left arm and to the left scapular region. A continuous thrill could be felt over the whole left side of the neck. The bruit and thrill were easily eliminated by compression of the common carotid artery. The mass in the neck became much less tense on obliteration of the artery and the pulse rate fell from 92 to 76 and the blood pressure changed from 110/70 to 110/84. Diagnosis of an arteriovenous fistula of the external carotid artery and internal jugular vein together with false venous sac was made.

Because it was apparent that considerable blood flow to this fistula came from both sides of the neck, preliminary ligation and division of the external carotid artery of the right side were done on Decem-

ber 28 1944. On January 4, 1945 the final operation was carried out under pentothal sodium anesthesia. An incision was made along the anterior border of the sternomastoid muscle from the angle of the jaw to the sternum (Fig. 12 b) and the muscle was retracted laterally. This exposed a tense and dilated venous sac. The common carotid artery was ligated and divided which relieved this tenseness to some extent. By careful dissection about the sac and retraction laterally three branches of the external carotid artery distal to the fistula could be ligated and divided. The internal jugular vein distal to the fistula was ligated. The internal jugular vein on the proximal side of the fistula was then ligated and divided. When this was done it became apparent that the fistula with the false sac could not be completely removed and therefore the sac was opened

and the clot evacuated. There was some bleeding from three openings in the sac which were evidently branches of the external carotid artery. Bleeding from them was easily controlled by the passage of interrupted sutures of silk. A portion of the sac wall was excised and the remainder was imbricated over the previously closed arterial openings (Fig. 12 c). The deep fascia and skin were closed with interrupted sutures of silk. The operation required 6½ hours. The patient's condition throughout the operation was good and there was no difficulty in his breathing. Following the operation there was considerable difficulty in his breathing and swallowing but from this he recovered gradually within a period of a week. A month later he was discharged from the service with considerable improvement in his hoarseness but none in sympathetic paralysis.

WAR INJURIES OF THE CHEST

EARLE B KAY MD F.A.C.S Major M.C. AUS and
RICHARD H MEADE Jr MD F.A.C.S Lt Col M.C. A.U.S

AN ANALYSIS of a large series of cases having war injuries of the chest as observed in an Army Chest Center in this country seems desirable. Reports on the early phases of chest injuries have been published (1, 2). The present analysis represents a study in retrospect of the first 500 consecutive patients in 2350 such patients seen. The material for this study was obtained from a careful review of the patients' field medical records, records of previous hospitalizations, and serial roentgenograms as presented by the patients at the time of admission to a chest surgical center in the Zone of the Interior. The course of such chest injuries is viewed from the point of vantage of their last hospitalization. These cases were analyzed as to the character of the original injury, initial treatment, complications, and subsequent treatment. An evaluation of operative and conservative therapy is made. Closure of thoracotomy wounds with and without drainage is discussed in relation to postoperative morbidity. Other aspects of the treatment of war chest injuries have been thoroughly covered in previous papers and will not be repeated. Such an analysis as this is felt to be of value in the treatment of similar injuries in the future. The condition of the patients upon arrival in this country as well as the more important phases of late treatment is described.

The lowered mortality from chest wounds in this war has been due to their excellent primary care. Chemotherapy and penicillin have aided but in themselves are no substitutes for sound surgical judgment. In some cases they may be detrimental to the patient's welfare if dependence on their protective ability leads the surgeon to take unnecessary risks.

Even though the mortality has been remarkably decreased from that in previous

years the morbidity could be further reduced. Several factors have contributed to the present morbidity. Among the factors to be discussed are (1) the delayed or ineffectual aspiration of hemothoraces; (2) the tendency to close contaminated chest wounds primarily without drainage; (3) ill timed or unwise thoracotomy; and (4) the tight closure of sucking wounds of the chest in the face of underlying bronchopulmonary fistulas.

The early treatment of chest wounds should be concerned primarily with the correction of the altered cardiorespiratory mechanism contributing to the shock of the patient and with the prevention of infection. There are only a few chest conditions which require immediate surgical intervention. These are large sucking wounds of the chest wall, tension pneumothorax, and uncontrollable bleeding. However, many emergency operations have been performed where these conditions have not existed. Many chest injuries fare better when they are treated by repeated, effectual thoracenteses. The type of injury as well as the nature of the offending agent is of importance in the decision as to immediate thoracotomy.

Certainly in explosive injuries causing large sucking wounds, hemorrhage, and extensive laceration of the lung with retained spicules of rib clothing and metal, thoracotomy is indicated. However, these comprise only a small proportion of the injuries seen.

ANALYSIS OF THE INITIAL CHEST CONDITIONS

The causative agent in the majority of cases was either shrapnel or shell fragments. A minority of the injuries was due to bullets. Table I lists the types of the initial conditions in 500 patients.

Hemothorax or hemopneumothorax of some degree occurred in 455 of the 500 patients with chest injuries. It is interesting to note that 19 patients with either perforating or penetrating wounds of the chest escaped without devel-

From the Thoracic Surgery Section, Kennedy General Hospital, Memphis, Tennessee.

TABLE I.—ANALYSIS OF INITIAL CHEST CONDITIONS*

Condition	N. of cases
Hemothorax	455
Significant foreign bodies	21
Sucking wounds	36
Combined chest-abdominal wounds	75
Bronchopleural fistulas	45
Penetrating or perforating injuries only	9
Lung contusion	5
Pericarditis with effusion	0
Tension pneumothorax	9
Blast injuries	8
Hematoma of the lung	4
Fractured sternum	4
Injuries to the esophagus	3
Injuries to the trachea	3

*The occurrence of some of these injuries may have been higher had no reference been made to them in the records available.

oping any detectable hemothorax. There were 211 retained foreign bodies. There were many more than this noted by roentgen examination but their size and location were such as not to be of clinical significance. One hundred and thirty-six sucking wounds of the chest wall were of such a degree as to require immediate closure. There were 62 extensive lacerations of the lung and 45 clinically significant bronchopleural fistulas. Transitory fistulas must have been present in other cases but apparently were not complicating factors. There were 75 combined chest-abdominal injuries. In several instances multiple abdominal organs were involved. The organs injured in the order of incidence were liver 40, spleen 16, stomach 15, kidney 9, small intestine and colon 7. The other initial injuries are self explanatory as noted in Table I.

The good results being obtained in patients with war chest injuries are due to the excellent organization providing the best care from the onset by the medical corps men and front line surgeons. The immediate use of morphine, tetanus toxoid, plasma, transfusions, sulfonamides, penicillin and followed when indicated by prompt débridement, thoracentesis and exploratory thoracotomy have saved many lives that would otherwise have been lost.

Four hundred and fifty five patients had some degree of hemothorax, many of which were associated with other conditions such as sucking wounds, lacerated lung tissue and retained foreign bodies. Others were uncon-

TABLE II.—TREATMENT OF 455 PATIENTS WITH HEMOTHORAX

	Number of cases	Patients developing infection	
		No.	Percent
I Group treated by thoracentesis	225	28	12.4
Eliminating 4 patients with bronchopleural fistulas who became infected	14	07	5
b Eliminating 13 patients (made completely tapped) (-no aspirates) who became infected		5	3
Eliminating groups a and b	201	1	0.5
II Group treated by operation	58	7	12.1
III Group with no definite treatment	7	20	43
Eliminating 6 patients with bronchopleural fistulas who became infected	66	24	36.4
b Eliminating 24 patients with small hemothoraces which healed spontaneously and 6 patients with bronchopleural fistulas	34	21	62

pliated. In a number it was impossible to determine the condition of the intrathoracic organs prior to operation.

The most severely injured patients had thoracotomies. In other instances, patients with less severe injuries were also operated upon. In a comparative analysis in retrospect from material obtained from the field medical records and serial roentgenograms it is difficult properly to evaluate all of the factors confronting the attending surgeon and influencing his decisions as to the type of therapy employed. In discussing results obtained in the treatment of hemothorax by various methods, hemothorax alone will be considered apart from the accompanying conditions. As may be noted in Table II, 225 of the 455 patients with hemothorax were treated conservatively by thoracentesis, 156 had thoracotomies and 74 had no definite treatment.

Results obtained with and without thoracentesis. The effectiveness of adequate repeated thoracenteses in the treatment of hemothorax is emphasized by the data in Table II. It is important to note that only 16.8 per cent of hemothoraces aspirated became infected, in comparison to 45.9 per cent of those not aspirated. The difference in the results obtained is even more striking if patients with bronchopleural fistulas and inadequate thora-

Fig. 1 a, A hemothorax secondary to a perforating wound of the right chest. b, The chest a few days following thoracotomy and hemostasis. No thoracotomy drainage

was employed because the amount of contamination was thought to be minimal. c, A fluid level in the right hemithorax indicative of a postoperative empyema.

centeses (only 1 to 2 aspirations) are eliminated from the first group. An incidence of infection of 6.9 per cent results in patients adequately treated. This may be compared to the second group in which thoracentesis was not used. If 6 patients with broncho-pulmonary fistulas are eliminated and 34 patients with only small collections of blood in the pleural space are not considered, an incidence of infection of 70 per cent results.

Operative versus conservative therapy in initial chest injury. Considerable advance has been made in thoracic surgery since the last war. The lowered mortality from chest wounds is, in part, due to the ability of present day surgeons to cope successfully with intrathoracic operations. However, as previously stated, there are only certain indications for immediate thoracotomy. The presence of a penetrating or perforating wound of the chest in itself is not an indication. Many operations designed to stop hemorrhage or to prevent infection have instead been followed by these as complications (Fig. 1). This is particularly apt to be true if the chest is closed without drainage.

One hundred fifty-six patients had initial thoracotomy débridement, hemostasis, and repair of the injured tissues within the first 24 to 48 hours. Of these 156 cases, 48.7 per cent were complicated by an infected hemothorax (Table II). 30 per cent by hemothorax relieved by thoracentesis and 6 per cent by

organized hemothorax. According to these figures, the operative group fared much worse than the group followed conservatively with thoracenteses, in which only 16.8 per cent of the patients required additional treatment. It is realized that the operative group included the severe injuries in which operative therapy was mandatory and the likelihood of complications great if operation had not been done, but it also included patients who would have done as well or better on conservative therapy alone. Of the 156 patients having early thoracotomies, in 66 no obvious indication for immediate operation could be found in their field medical records. The majority of these had retained foreign bodies in addition to a hemothorax. Sixteen patients were found at the time of operation to have lacerated lung tissue. A number of these patients had their wounds closed without drainage and did not receive adequate postoperative thoracenteses. Many of these patients developed infection which required drainage (Fig. 2). No mention is made of chemotherapy (sulfonamides and penicillin) for this was employed in all groups.

Comparison of results obtained in patients having thoracotomies closed with drainage and without drainage. There were 189 patients in all who had thoracotomies prior to arrival in this country. This includes 33 patients who were operated upon at a later date in addition to the initial 156. In 81 patients wounds were closed with drainage and in 108 without. In

Fig. 2. Roentgenograms illustrating penetrating bullet wound of the left chest. The bullet is noted in the left apex. An immediate thoracotomy was performed for hemostasis and to remove the bullet. The bullet was so located in the mediastinum as to prevent its removal. The chest was closed without drainage. a, A postoperative hemothorax. This later became infected and was treated by open thoracotomy drainage. b, The resulting total empyema space.

Fig. 3. Roentgenograms illustrating penetrating wound of the right chest resulting in retained shell fragment and a hemothorax. a, Condition of chest prior to operation. b, A postoperative pneumothorax secondary to a bronchopleural fistula. those closed with drainage 82.7 per cent healed without requiring secondary operations in contrast to only 43.5 per cent of those closed without drainage.

The patients who were drained and yet became infected had the most severe injuries. There was an average length of healing in the first group of 10 weeks as compared to 14 weeks in the second group. Even though 43.5 per cent of the patients closed without drain-

age healed primarily the higher incidence of postoperative infection requiring secondary operations and the longer period of convalescence in those who became infected makes this type of treatment less desirable than the use of postoperative drainage.

Conditions under which a surgeon must care for the wounded at the battlefield do not always allow him to supervise the postoperative care for a sufficiently long period of

TABLE III.—THORACOTOMIES CLOSED WITH AND WITHOUT DRAINAGE

	Closed with drainage 81	Closed without drainage 108
Number of cases

Percentage requiring secondary operations	17.3	56.5
Average duration of healing	10 weeks	14 weeks

time, nor allow the thorough aspirations of a hemothorax before the patient must be evacuated elsewhere. It seems far safer therefore to employ routinely water seal drainage after thoracotomies. This would be followed by less risk to life and lowered morbidity and would require considerably less of the surgeon's time and attention than would repeated post-operative thoracenteses. During transportation the thoracotomy tube could be clamped and the bottle temporarily disconnected or a flapper type drain used.

Foreign bodies. Of the original 211 retained foreign bodies, 47 were removed at the time of the original operation and 33 after an interval of several weeks. In many patients the foreign body was removed incidental to débridement, hemostasis and repair of lacerated lung tissue while in others the operation was designed primarily for the removal of the foreign body. In this latter group the chest was frequently closed without drainage because the extent of injury was not great. In the process of removing the foreign body bronchopleural fistulas frequently were created and these were not adequately repaired, as demonstrated in Figure 3. The incidence of postoperative infection in this group alone was 30 per cent.

There is considerable difference of opinion as to the clinical significance of metallic foreign bodies and the indications for their removal. The chief reason for removing pulmonary foreign bodies is the possible development of hemorrhage or infection. Of the entire group only 8 were later associated with hemoptysis, 7 with lung abscesses, 6 with pneumonitis and 8 with draining sinuses. These conditions occurred for the most part within 2 to 4 weeks following injury. Those foreign bodies associated with infection were usually found at operation to be intermingled with other debris such as particles of clothing

Fig. 4. Diagrammatic illustration of the emergency treatment, b, by packing with vaseline gauze and tight application of adhesive tape to sucking wound illustrated in a. c, Diagrammatic demonstration of the definitive treatment of sucking wounds of the chest wall by débridement and partial closure including the pleura and muscle layer but leaving subcutaneous adipose tissue and skin open. An intercostal water seal thoracotomy tube is inserted to drain the inevitable hemothorax.

and dirt which probably was the cause of the infection rather than the metallic foreign body itself. Only experience over a longer period of time will enable the surgeon to evaluate the late results of residual foreign bodies and the advisability of their removal.

SUCKING WOUNDS OF THE CHEST WALL

There were many more sucking wounds of the chest wall than the 136 listed but these were small enough to be of no clinical significance and responded promptly to either packing or débridement and primary closure.

Fig. 5. Serial roentgenograms. a. An early infected hemothorax with mediastinal shift to the opposite side. b. A residual empyema space following early open

thoracotomy drainage. The appearance of the healed chest following continuous suction therapy over a period of 4 months.

There was between 5 to 10 per cent infection in such wounds closed primarily. In several instances tension pneumothorax developed after closure of the sucking wound when underlying bronchopleural fistulas were not recognized. In the larger sucking wounds of the chest wall emergency closure by packing was followed almost universally by débridement and primary closure. Fifty-seven per cent had thoracotomies in addition to closure of the sucking wounds. Several patients with sucking wounds had only partial closure of the chest wall following débridement in conjunction with intercostal water seal drainage as demonstrated in Figure 4. The convalescence of these patients was the least complicated of all.

INJURIES TO THE ESOPHAGUS AND TRACHEA

There were 3 injuries to the cervical esophagus and 2 to the upper end of the trachea in the first 500 patients analyzed. Eight additional cases have since been seen. No injury to the thoracic esophagus was noted even though in a number of instances ragged shell fragments have lodged in the posterior mediastinum close to the esophagus (Fig. 8d). The high mortality resulting from mediastinitis and hemorrhage associated with such injuries accounts for the few patients seen in the Zone of the Interior. Three patients had immediate tracheotomies and 4 patients gastrostomies within 4 to 10 days time. All of these injuries were complicated by esophageal fistulas and abscesses requiring drainage.

Fig. 6. Roentgenograms demonstrating a. an infected organized hemothorax and b. the postoperative result following decortication.

TABLE IV—COMPLICATIONS (CHEST)

Complications	N
Infected hemothorax	144
Hemothorax	47
Organized hemothorax	49
Bronchopleural fistula	36
Subphrenic abscess	12
Pneumonitis and lung abscess about foreign body	11
Tension pneumothorax	9
Pneumonitis and abscess at site of hematoma	4
Infected costal cartilage	7
Atelectasis	9
Pulmonary infarct	3
Bronchopneumonia	5
Hemoptysis secondary to foreign body	8
Pericarditis with effusion	8
Suppurative pericarditis	2
Pericardial tamponade	1
Esophageal fistula with paracervical abscess	3
Diaphragmatic hernia	5

Two patients developed esophageal strictures requiring dilatation. The tracheotomy tubes were removed within 3 to 4 weeks with no further difficulty in breathing. Four of the 6 patients also had recurrent laryngeal nerve paralysis that persisted. The eventual outcome in these 6 patients was satisfactory.

COMBINED CHEST ABDOMINAL INJURIES

The majority of the chest abdominal injuries were successfully treated through a transthoracic approach. Others were explored through the abdomen. In case of doubt as to the extent and location of the abdominal injury the abdominal approach allows better exploration. The diagnosis of a concomitant abdominal injury is frequently difficult to make for diaphragmatic and intercostal irritation frequently give abdominal pain, tenderness and muscle spasm. In combined injuries the abdomen deserves primary attention if the chest is stable. Only when large sucking wounds of the chest wall, tension pneumothorax, pericardial tamponade or rapidly developing hemothorax associated with shock not relieved by conservative therapy are present should the chest condition be given first consideration. Intratracheal anesthesia should be employed in all operations for combined chest-abdominal injuries regardless of approach for if there is a tear of the diaphragm atmospheric air from the abdominal incision may cause collapse of the lung on the affected side and even tension pneumothorax. When injuries to the liver are explored transpleur-

Fig. 7. Roentgenogram demonstrating lipiodol visualization of bronchopleural fistula, narrow empyema tract, and drainage site some distance from fistula.

ally both the subphrenic and pleural space should be drained. When this precaution is not taken bile empyema and subphrenic abscess are frequent developments. Bile empyema occurred in 14 instances. The most significant ones followed closure of the wound without drainage.

The liver appears to tolerate the presence of metallic foreign bodies very well. Liver abscess secondary to a metallic foreign body was not noted in this series even though biliary drainage was present following injury in a number of patients. In injuries to the lower chest careful urinalysis for the presence of blood is indicated. Intravenous pyelograms have occasionally illustrated defects in the renal pelvis secondary to such injuries.

Complications—chest. Infected hemothorax was the largest single complication. Fifty-three per cent of 144 cases were secondary to thoracotomies. Many of the thoracotomy wounds were closed without drainage and because of the necessity of evacuation to other hospitals thoracostomies were often delayed or infrequent. Forty-seven patients developed postoperative hemothorax. All of this group responded favorably with repeated aspirations. Forty-nine patients developed organized hemothorax. Twenty of these had only one aspiration or none at all and 7 had only two aspirations. 9 followed previous thoracotomies.

The majority of the 36 bronchopleural fistulas were secondary to severe injuries. 8 were secondary to removal of foreign bodies and 6 were noted only after the development of

Fig. 8. Roentgenograms demonstrating pneumonia and abscess. b and c, foreign bodies in contact with the esophagus. d, foreign body associated with pneumonia.

empyema. Eleven patients had roentgen evidence of either pneumonia or lung abscess at the site of foreign bodies. In 4 patients pulmonary hematomas became infected, liquefied and required drainage. The other complications are self-explanatory as noted in Table IV. The surgical treatment of the complications is tabulated in Table V as follows:

TABLE V.—TREATMENT OF COMPLICATIONS

Treatment	No. cases
Thoracentesis	47
Drainage empyema	5
Radical resection	46
Decortication	49
Closure bronchopleural fistula	0
Drainage subphrenic abscess	2
Repair of diaphragmatic hernia	3
Drainage lung abscess	3
Pericardial pericarditis	1
Drainage suppurative pericarditis	2
Drainage pericardial tamponade	4
Resection of osteochondritis	4

EMPYEMA

Etiology of empyema. One hundred fifty-one patients developed empyema secondary to the chest injury. In some, several factors appeared to contribute, such as bronchopleural fistula or extensive injury with considerable contamination in patients whose wounds were closed without drainage following operation. In 41.2 per cent the cause was directly concerned with some aspect of the injury such as its severity, extensive contamination or laceration of the lung with bronchopleural fistula. In 58.8 per cent failure to provide adequate aspiration of a hemothorax in the nonoperative cases or postoperative water seal drainage in the operative group was responsible, either wholly or in part, for the development of the empyema. Of this 58.8 per cent 31.4 per cent had thoracenteses

Fig. 9. Roentgenograms demonstrating a, a lung abscess associated with a metallic foreign body. At time of operation clothing and other debris were found in the abscess cavity. b, A large foreign body partially embedded in the lung parenchyma and protruding into the empyema cavity. c and d, Large foreign bodies in the lung parenchyma associated with empyemas.

without postoperative drainage 9.4 per cent too early removal of the thoracotomy tube and 18 per cent inadequate thoracenteses (0-2 aspirations). No patient operated upon developed an empyema of clinical significance as a result of water seal drainage. This analysis suggests that the incidence of empyema could have been appreciably reduced if adequate water seal drainage had been provided. The average interval prior to drainage of the empyema was $3\frac{1}{2}$ weeks.

Condition on admission to chest surgical center. Certain aspects of value in the late treatment of these conditions will be discussed. The majority of the chronic empyemas are adequately drained and in a state of healing when admitted. Those that are not adequately

drained are redrained. Most are either small or moderate in size. During the early phases of the war there was a tendency to perform early open thoracotomy for infected hemothorax. Total empyema spaces were a fire

TABLE VI.—CONDITION ON ADMISSION TO CHEST SURGICAL CENTER

Condition	No. of cases	Percentage
Healed	374	62.8
Chronic empyema	82	16.4
Foreign bodies	49	9.8
Bronchopleural fistula	36	7.2
Draining sinus	26	5.2
Organized hemothorax	12	2.4
Hemothorax	9	1.8
Diaphragmatic hernia	4	0.8
Esophageal fistula and para-esophageal abscess	3	0.6
Pericardial effusion	2	0.4

Fig. 11 Photographic illustrations of a decortication

fibrin on visceral pleura b, Easily obtainable cleavage
 plane between fibrous encasement and visceral pleura.
 c, Re-expansion of lung with positive pressure anesthesia.

moved if readily obtainable at the time of drainage (Fig 9) If not then they are removed at a later date if causing a drainage sinus Foreign bodies causing hemoptysis or intercostal pain are removed if it can be shown that the foreign body is directly responsible (Fig 10)

Only occasionally the psychological factors of fear and pain are such as to indicate the removal of a foreign body that would not otherwise be removed Foreign bodies when unaccompanied by other debris have been found at operation to be associated with surprisingly little reaction and no infection Those in contact with large blood vessels have been well encapsulated in fibrous tissue Because of these observations the tendency has been to remove fewer and fewer foreign bodies and then only when indicated Tetanus toxoid is always given preoperatively as well as penicillin which is also continued for 4 to 5 days postoperatively At the time of admission to this center 4 patients still had either pneumonitis or lung abscesses 3 had hemoptysis and 4 had draining sinuses The onset in most of these was shortly after injury No evidence of infection has as yet been seen to develop in those patients having retained foreign bodies shown roentgenologically to be free of infection for as long as 2 to 3 months Two patients

bad gross hemoptysis 6 months to a year after injury

Decortication in cases of organized hemothorax has enjoyed considerable popularity and is indeed responsible for the amazing results obtained in many individuals who would otherwise have suffered from a chronic fibrothorax In 8 per cent of the hemothorax patients clotting of the blood occurred to the extent of preventing evacuation of the blood by aspiration In neglected cases the lung is compressed against the mediastinum by an encasement of organized fibrin which prevents the lung from re-expanding immobilizes the diaphragm and lines the parietal surface This layer of fibrin in some instances may be 15 centimeters in thickness The pleural cavity usually contains a jelly like fibrinous mass The operation of decortication as shown (Fig 11) consists of developing an easily obtainable cleavage plane between the fibrous encasement and the adjacent visceral pleura pericardium diaphragm and chest wall from which it can be easily separated allowing re-expansion of the lung When this layer is first incised as shown in Fig 11 b the line of incision quickly gaps and lung tissue herniates through the opening The best results are those done early (4 to 6 weeks) After the lung has been allowed to remain collapsed for

3 months or more some fibrosis of the parenchyma frequently takes place causing delayed postoperative re-expansion

SUMMARY

An analysis of 500 consecutive patients with war injuries of the chest is presented. The course of these injuries is viewed from the point of vantage of their last hospitalization. The material for the study was obtained from a careful review of the patients' field medical records, records of previous hospitalizations and serial roentgenograms as presented by the patients at the time of admission to a chest surgical center in the Zone of the Interior. The character of the original injury, initial treatment and complications are described. An evaluation of operative and conservative therapy of chest injuries is made.

Closure of thoracotomy wounds with and without drainage is discussed in relation to postoperative morbidity. The condition of the patients upon arrival in this country as well as the more important phases of late treatment is described.

The effectiveness of repeated thoracentesis in the treatment of 225 patients with hemothorax is apparent in the incidence of infection of only 16.8 per cent as compared to an incidence of infection of 45.9 per cent in 74 patients not aspirated.

Early thoracotomies employed in the treatment of chest injuries designed to stop hemorrhage or to prevent infection have frequently been followed by these as complications. This is particularly apt to be true if the chest is

closed without drainage. Of the 156 initial thoracotomies 48.7 per cent were complicated by an infected hemothorax, 30 per cent by a hemothorax and 6 per cent by an organized hemothorax. The operative group includes the more severe injuries and the likelihood of complications is greater, but it also includes a number of patients that could have been treated as well by conservative means.

The advantage of postoperative water seal drainage over primary closure of thoracotomy operations without providing drainage is demonstrated by an incidence of healing without requiring secondary operations of 82.7 per cent in patients drained in contrast to only 43.5 per cent in those not drained. Conditions under which a surgeon must care for the wounded at the battle front does not always allow time to supervise the postoperative care for a sufficiently long period of time nor allow the thorough aspirations of a hemothorax before the patient must be evacuated elsewhere. It seems far safer therefore to employ water seal drainage routinely after such thoracotomies.

The treatment of foreign bodies sucking wounds of the chest wall, injuries to the esophagus and trachea, as well as combined chest abdominal injuries is discussed.

The late treatment of chronic empyema, bronchopleural fistulas, intrathoracic foreign bodies and organized hemothorax is described.

INTRAVENOUS GELATIN FOR NUTRITIONAL PURPOSES

Clinical and Experimental Studies

ALEXANDER BRUNSCHWIG M.D., F.A.C.S. SABRA NICHOLS S.B. and
ROBERT BIGELOW M.D., Chicago, Illinois

GELATIN is an incomplete protein since it does not include all the amino acids essential for normal growth and reproduction. Recently certain gelatins have been employed in the treatment of shock as a plasma or "blood substitute." The following report is concerned with animal experiments and clinical studies employing gelatin as a parenteral nitrogenous nutriment.

The gelatin employed has been previously described.¹ It was prepared from pigskin autoclaved several times and made up into an 8 per cent solution in normal saline.

As the purpose of this study was to determine whether intravenous gelatin is utilized for synthesis of the organism's own proteins (plasma proteins in particular) certain control studies were necessary. Since gelatin is a colloid, the first step was to observe the effects of repeated intravenous injections of an inert non nitrogenous colloid. Gum acacia, 6 per cent in saline was injected daily intravenously in 2 dogs weighing 7.7 and 7.1 kilograms respectively. The quantities injected varied from 200 to 400 cubic centimeters. The hematocrit readings prior to injection were 39 per cent and 35 per cent, respectively. After 6 days these values fell to 14 per cent in each instance. The preliminary plasma protein levels were 5.1 and 5.65 grams per cent respectively, and after 8 days' injection fell to 2.27 and 1.57 grams per cent, respectively, and were maintained at these levels by repeated injections. The reduction in levels of circulating plasma proteins paralleled roughly the reductions in hematocrit readings. Brom sulfalein liver function test in 1 animal after 13 days' injection was within normal limits. These studies were interpreted to indicate that an inert colloid could be injected to dilute

the blood plasma and that plasma protein levels were correspondingly reduced because outpouring of plasma from the tissues into the circulation. If it did occur at all, was insufficient to elevate the plasma protein level above that expected from the dilution.

Another control observation was the determination of the dilution effects of gelatin injected daily as has been described. It was not anticipated that gelatin alone would suffice as an efficient nutriment since it does not include all essential amino acids. It was necessary however to determine if gelatin repeatedly injected would afford hemodilution as did gum acacia. The data obtained in 2 animals are summarized in Table I. Prior to these experiments the animals were depleted of protein by maintenance on a low nitrogen diet (1 gm. of the diet contained 1 mgm. nitrogen).

The results show that hemodilution resulting from repeated injections of gelatin is not comparable in degree with that observed following gum acacia, in that the latter probably remains in the circulation for a longer period.

Still another type of control observation carried out was the demonstration that gelatin injected intravenously was not inert but was at least partially catabolized by the organism. For example in 1 patient receiving nothing by mouth and only saline solution by vein the average daily urea nitrogen excretion was 2.8 grams for 3 days when 11 grams of gelatin were injected each day for 3 days, the average daily urea nitrogen excretion was 7.5 grams and on the subsequent 3 days when saline only was again injected the urea nitrogen excretion was 3.2 grams per day. Explanations other than that the increased urea excretion was derived from catabolism of some of the gelatin would appear farfetched.

In a study to determine the utilization of a given nutriment administered intravenously it is necessary to determine its efficiency when

Brunschwig, A., Corbin, N. and Johnston, C.D. Ann. Surg. 93, 7 & 1918-1920.
From the Department of Surgery University of Chicago.

Patient K., No. 344120, female, aged 34 years, convalescent from a radical colectomy and enterectomy performed for extensive regional enteritis was markedly depleted before operation due to severe diarrhea.

During a period of 7 days observation the following facts were noted

Average daily nitrogen in diet—grams	11.0
Average daily nitrogen (intravenous) gelatin—grams	11.2
Average daily calories in diet	812
Average daily total nitrogen intake—grams	22.2
Average daily nitrogen excretion—grams	14.7
Average daily nitrogen balance	+7.5

The above depleted convalescent patient was enabled rapidly to achieve an average daily positive nitrogen balance of 7.5 grams. Seven months after operation she remains well.

Similar data in another patient again indicate the value of intravenous gelatin in increasing nitrogen retention. A period of 6 days observation while gelatin was administered was followed by a period of 5 days when gelatin was not injected.

Patient R., No. 305306 female, aged 35 years, a convalescent from excision of the head of the pancreas and duodenum for carcinoma of the former. Six months after operation patient is well.

	Period I 6 days	Period II 5 days
Average daily (intravenous) gelatin—grams	1.5	0
Average daily nitrogen in diet—grams	5	7.4
Average daily calories in diet	820	1573
Average daily total nitrogen intake—grams	16.5	7.4
Average daily nitrogen excretion—grams	12.8	6.3
Average daily nitrogen balance—grams	+3.7	+1.1

Data in a third patient who received all nutriment intravenously follow

Patient Nels No. 356063, male, aged 58 years was suffering from carcinomatosis primary in the stomach.

	Period I 9 days	Period II 4 days
Average daily (intravenous) gelatin—grams	11.2	11.2
Average daily nitrogen (intravenous) casein digest—grams	6.0	6.0
Total nitrogen (intravenous)—grams	17.2	17.2
Intravenous glucose—grams	150	200
Average daily nitrogen excretion—grams	16.3	15.3
Average daily nitrogen balance—grams	+7	-4.1

A slight positive nitrogen balance was possible when gelatin and casein digest were injected, whereas when gelatin alone was injected there was pronounced negative balance. This may be explained by the inadequacy of gelatin alone as a nitrogenous nutriment whereas combined with casein digest all essential amino acids were afforded.

DISCUSSION

Parenteral nutrition by means of nitrogenous substances is in its early stages of development. Undoubtedly as progress in this field continues, newer types of solutions will be developed to afford increased efficiency of utilization and to include factors the essentiality of which are not as yet appreciated.

The studies summarized herein indicate that certain gelatins may be employed for the parenteral administration of nitrogen and that nitrogen in such form is anabolically utilized. The principle demonstrated is that a non-antigenic protein may be administered parenterally and is at least partially utilized if essential amino acids which it may not contain are otherwise available.

SUMMARY

Experimental studies in dogs indicate that a certain type of gelatin administered intravenously is at least partially utilized for regeneration of plasma proteins.

Clinical experience indicates that intravenous gelatin constitutes one method by which nitrogenous substances for nutritional purposes may be administered.

INDICATIONS FOR ROENTGEN THERAPY OF BLADDER CARCINOMAS

Recognition of Suitable Cases

FRANZ BUSCHKE, M D and SIMEON T CANTRIL, M.D Seattle, Washington

RADIATION therapy of carcinoma of the bladder comprises several procedures external roentgen therapy contact roentgen therapy through the suprapubic wound interstitial irradiation by means of removable radium needles or implantation of radon seeds into the tumor The following discussion deals exclusively with external roentgen therapy of the bladder in an attempt to gain a working basis for indications of this type of treatment in the management of bladder carcinoma in contrast to other radiological and surgical procedures

Roentgen therapy of cancer in general has two distinct aims palliation or permanent cure. Palliative and radical curative roentgen therapy differ fundamentally in indications and technique in spite of the quite widespread misconception that an incomplete course of irradiation might still afford some palliation even if it does not completely sterilize the cancer Usually in such instances the added injury of incomplete irradiation will rather aggravate the condition

Palliative roentgen therapy to be sure has its well defined place in the management of certain incurable cancerous manifestations but its scope is much narrower than is generally assumed and patients have to be selected as carefully as for the radical procedure In the treatment of those cancers of the bladder which are considered incurable by surgical or radical radiological procedures because of the extension of the disease or the general condition radiation therapy with the purpose of palliation only has no place It is useless and in many instances harmful The amount of irradiation necessary to produce sufficient tumor response to cause even an appreciable retardation of growth will, if the tumor remains uncontrolled cause so much discomfort

From the Tumor Institute of the Swedish Hospital, Seattle.

by increased frequency and pain with corresponding deterioration of the general condition that the term "palliative" becomes meaningless. Very occasionally the use of irradiation as a hemostyptic agent may be considered. Usually, however the hemostyptic effect if accomplished at all will be of only very short duration unless a marked actual tumor response is induced. In short the procedure necessary to produce even a temporary tumor regression for the types of cancer encountered in the bladder is of a magnitude out of proportion to its possible results even in cases in which it does not actually aggravate the condition. The damnable practice of giving a few light treatments for psychological reasons in hopeless cases will only discredit the procedure in the minds of those surgeons and urologists who do not yet appreciate the value of radical roentgen therapy for carefully selected suitable cases.

Radical roentgen therapy, in the meaning of this term as we shall presently define it is young. It dates from 1922 when Regaud, Coutard and Hautant demonstrated 6 patients with inoperable cancer of the larynx treated and cured by x ray therapy. For the first time the fact was established that for certain types of tumors radiation therapy is superior to surgery that surgery and radiation therapy do not compete with each other that each procedure has its own indications. The fundamental principle of radical radiation therapy which Coutard has taught us is the careful adaptation of the treatment to the requirements of the individual patient (type of tumor extension general condition, response to treatment) under the guidance of detailed daily examination. In this way—and in this way only—is it possible to push the dose to the necessary tumor sterilizing level without causing intolerable permanent damage to the sur-

rounding structures. During the two decades that followed this fundamental and epochal demonstration we have learned to apply this type of treatment to certain tumors—such as those of the larynx, pharynx, and cervix—with a degree of certainty that their treatment has passed the stage of the clinical experiment and is now considered as a well established clinical procedure not a last resort in hopeless cases. Accumulated experience has taught us to recognize certain factors as decisive for the recognition of suitable cases for the determination of the prognosis and for the actual conduct of therapy: the histological type of the tumor, its exact location and extension and the general condition of the patient. We have learned for example that the all inclusive diagnosis of carcinoma of the larynx is meaningless unless it is qualified by a detailed description of the place of origin (true cord, false cord, epiglottis etc.) and extension (mobility or fixation, invasion of muscle or cartilage etc.)

In the treatment of cancers of the bladder this stage has not yet been reached. In certain instances bladder cancers have responded to roentgen therapy satisfactorily enough to demonstrate the essential radiovulnerability of these tumors and to encourage further attempts. As a whole however it seems from a review of the literature that the treatment has been given in a more or less haphazard and unsystematic fashion in regard to the selection of cases and the technique used. In general one gains the impression that more often than not roentgen therapy in bladder carcinoma is resorted to only as a last attempt after the urologist has failed.

The main reason for this unsatisfactory state of affairs is probably an insufficient co-operation between the urologist and the radiation therapist. As has been pointed out before the fundamental requirement for radical roentgen therapy is a careful adaptation of the procedure to the requirement of the individual case. We have seen radiologists treating bladder carcinomas without ever having looked into these bladders or without having studied the microscopic section of the biopsy. It is impossible to treat adequately a carcinoma of the larynx or cervix without de-

tailed appraisal of the individual situation by the radiotherapist himself: the same is naturally true for carcinoma of the bladder. The personal examination cannot be fully replaced even by the best description. Naturally the radiation therapist cannot be a specialist in all fields but he must have enough working knowledge in the borderline specialties to enable him to interpret intelligently the findings in close collaboration with the respective specialist. In the conduct of treatment for carcinoma of the bladder in comparison to larynx and cervix, we are somewhat handicapped by the impossibility of regular inspection of the local response since of course frequent cystoscopies during and immediately following treatment even in the best hands would aggravate the treatment reaction and induce serious complications. But a detailed preliminary examination by the radiation therapist in collaboration with the urologist is essential.

From the experience with other tumors it can be assumed that probably only certain types of bladder carcinomas, if any, would be suitable for this kind of treatment while others may be more benefited by other procedures such as surgical excision, fulguration or interstitial radium application. Real progress can be expected only by correlating the success or failure with the details of the individual case treated—with respect to type, location, extension of tumor, general condition of the patient, complicating features such as infection and obstruction as well as considering the details of the procedure used.

With these ideas in mind we analyzed in 1941 the 44 cases of carcinoma of the bladder treated in this Institute between 1934 and 1939 with external supervoltage therapy (1). At that time we reached certain tentative conclusions regarding contraindications and indications which since then have been used as a working basis to guide us in the selection of suitable cases. Again in 1942 we reviewed our material of 52 patients treated between 1934 and 1940 (2). A summary of the entire group of patients treated by this procedure during the 10 year period between 1934 and 1943 is given in Table I.

The experience of others (3, 4, 5, 6) as well as our own in certain carcinomas of the blad-

der demonstrates the possibility of cure with external roentgen therapy. The details of the apparently cured cases including photomicrographs were presented in our previous reports. Our increased experience since the first reports has substantiated our conclusions regarding the contraindications for this procedure. Regarding indications we have to modify our conclusions somewhat in so far as we have seen some patients apparently cured who have shown types of tumors originally considered unsuitable for this type of therapy.

In analyzing the failures as well as the successes we are led to the conclusion that 5 main factors seem to be decisive for the indication for roentgen therapy (1) the biological type of tumor (2) extension of the disease (3) general condition of the patient (4) previous therapy of any kind (5) technique of treatment.

THE BIOLOGICAL TYPE OF TUMOR

As in malignant tumors of other organs the biological type of tumor is probably the most important single factor. The possibility of sterilizing certain malignant tumors by ionizing radiation is due to one of nature's whims which has endowed certain normal and abnormal cells with a sensitivity to this type of irradiation. By trial and error on the basis of empirical experience we have learned to recognize certain tumors as radiovulnerable and others as resistant to ionizing irradiation. In carcinoma of the bladder our experience is still too young to make final conclusions. It seems however that the tumors most suitable for irradiation are the papillary carcinomas without invasion of the bladder wall. In our former reports we have stated that all of our patients treated successfully belong to this group. At that time we emphasized that we were not in full agreement with other reports in the literature in which successful treatment of invasive bladder tumors by x ray therapy was reported. During the last years we have had occasion to treat 2 patients who belong in this group and whom we first very reluctantly accepted for treatment because of the invasive character of the tumor. So far they have shown so complete and persistent a disappearance of the tumor that in all likelihood they will remain cured. In these cases the diagnosis

TABLE 1—SUMMARY OF 69 CASES DURING 10 YEAR PERIOD 1934-1943

Year	No treated	No well to date	Dead or alive with active disease	Lost
1934	0	3	3	
1935		7	6	3
1936	1

1943	3			
Total	49		35	

of the invasive character was made on the cystoscopic as well as the microscopic evidence. We have however no way to tell whether the invasion in these cases extended into the muscular structures of the bladder or was limited to the mucous membrane itself. Experience with cancers of other organs has shown that the curability decreases with progressive invasion of the adjoining muscular structures. We believe therefore that the most suitable types for radiation therapy are the papillary carcinomas without marked invasion of the bladder wall. It must be kept in mind that this invasion may not be demonstrable at the first cystoscopy or by preliminary biopsy examinations because only the papillary portion of the tumor intruding into the bladder may be resected for biopsy. An experienced urologist however can recognize the bladder wall involvement to a certain degree. The picture may be masked by a secondary inflammatory reaction and in these instances the infiltration may be less real than apparent. On the other hand certain growths can be definitely recognized as infiltrating growths by cystoscopic examination, palpatory findings and histological examination. We do not believe that a cancer of the bladder once it has deeply infiltrated the muscular structures or has extended beyond the bladder itself is still a suitable object for radiation therapy. Some infiltrative growths as long as the infiltration remains fairly superficial may still occasionally be sterilized.

On the other hand we have seen recurrences in cases of very low grade papillary carcinomas (which by some pathologists would be termed papilloma or malignant papilloma) following a course of supposedly adequate therapy. On the basis of this yet very limited experience it would seem that the most suitable carcinomas are the recurrent papillary carcinomas of a moderate degree of differentiation, those which the urologist considers as beyond his control by repeated fulguration.

EXTENSION OF THE DISEASE

From the foregoing discussion it becomes evident that regardless of the type of tumor, the extension of the disease will have a marked effect on the outcome. While naturally cases with demonstrable distant metastases are beyond treatment one might at times be tempted to treat those which locally have extended beyond the bladder proper. If we feel that the invasion of the bladder muscle itself already demarcates the limits of curability by roentgen therapy obviously cases with involvement of the perivesicular structures are beyond therapeutic approach. In former years in practically all patients seen the disease had extended beyond the surgeon's reach. It was for this reason that they were referred for roentgen therapy. During recent years the situation has changed and due to our increased experience with indications and contraindications and in closer co-operation with the urologists we now receive patients for treatment who technically could still be treated by surgical procedures but for whom the urologists now too feel that roentgen therapy may offer a better chance because of the recurrent character of this type of lesion.

GENERAL CONDITION OF THE PATIENT

As in roentgen therapy for other cancer we have seen that the appraisal of the general condition of the patient quite generally is underestimated in the decision as to indications for roentgen therapy. Consequently it is believed that if a patient is unsuitable for surgery because of his general condition roentgen therapy might still be attempted. Very rarely should the general condition be a decisive factor for determination of surgical

versus radiological indications. With the exception of occasional instances of specific contraindications, such as cardiovascular disease which prohibits surgery patients who are refused surgery on account of their general condition will not support a treatment of such magnitude as radiation therapy. In many a physician's mind radiation therapy of cancer still seems to be a kind of glorified ultraviolet or diathermy. It must be realized that radical radiation therapy with the purpose of cure represents a procedure of such formidable magnitude that it will be supported only by patients in good general condition. It is mainly the lack of appreciation of the meaning of the term radical roentgen therapy which leads physicians and patients alike to believe that a few light treatments might accomplish miraculous results. Actually the treatment of a cancer of the bladder requires daily treatment for about 6 to 8 weeks. Following the therapy a bladder reaction will develop leading to frequency of urination and pain. The intensity of this reaction varies within wide limits. It depends partly on the location of the tumor, the condition of the bladder mucosa in general and on the individual sensitivity. If the tumor is located in the dome the reaction usually will be less marked than if it is located in the trigonal region encroaching on the urethral orifice. A tumor located in the lower most portion of the bladder necessitating irradiation of the prostatic urethra will lead to a very marked reaction with considerable distress. The reaction in men usually is more intense than in women. Marked infection of the bladder mucosa outside of the tumorous portion will also markedly increase the intensity of the bladder reaction. If this is associated with a urethral obstruction by either tumor or prostate interfering with bladder drainage the reaction may be so intense that the actual deterioration of the patient's condition becomes dangerous. Frequency and pain under these conditions interferes so markedly with the patient's general condition that it makes the continuance of adequate radiation therapy impossible. We now refuse patients for treatment in whom either a severe infection is present or adequate drainage cannot be established. In cases in which it is possible

to remove either the enlarged prostrate or the occluding tumor mass to re-establish drainage we ask for this procedure prior to roentgen therapy. If the drainage is either adequate from the beginning or is re-established, one might cautiously begin radiation therapy for the accompanying infection. The treatment itself in some cases may improve the infection at which time the more intense therapy for the carcinoma can be established. However if we do not succeed in combating the infection before the more intense roentgen therapy begins we are very soon handicapped in the adequate conduct of treatment which will not be successful.

From this discussion it becomes evident that patients in a poor general condition are not suitable objects for this kind of therapy. We have found however, that age in itself in an otherwise well preserved body without accompanying infection and not too far advanced disease does not represent an absolute contraindication to the treatment.

PREVIOUS THERAPY

Suprapubic operation preceding roentgen therapy considerably lowers the possibility of adequate irradiation. We have observed the breakdown of a suprapubic scar shortly after irradiation in 2 patients. In both cases the contributing factor to the breakdown could be found in an increased intravascular pressure from interference with adequate drainage. We believe however that in spite of these additional difficulties the previous suprapubic operation itself is a severe handicap to adequate irradiation. If roentgen therapy is considered we feel therefore that either a suprapubic cystotomy should be avoided or should be done high enough to keep the scar outside the field of irradiation. This latter procedure may sometimes be used when an attempt at suprapubic resection may be preferable yet a recurrence of a type of carcinoma suitable for roentgen therapy later on may be considered.

Occasionally patients have been referred after unsuccessful treatment by means of interstitial irradiation. As in all other kinds of carcinoma these patients are not suitable for further irradiation. Cancer therapy by irradiation is an all or none procedure. If the first

attempt fails success can practically never be expected by further irradiation. The tissues do not tolerate the dose necessary for sterilization of the tumor after they have received previous radiation therapy. The tumor itself has become more radioresistant and due to fibrosis is less amenable to further irradiation. If interstitial irradiation has been given by means of permanently implanted seeds the presence of the metal with a secondary irradiation in its immediate neighborhood will add to the necrotic effect of the irradiation and jeopardize the treatment even more than previous radiation therapy by other procedures. It is obvious therefore that these patients should be refused for roentgen therapy.

The situation is somewhat different with regard to previous fulguration. Indeed the most favorable cases for roentgen therapy of the bladder are apparently those that show recurrent papillary carcinoma. In these instances fulguration has usually been attempted and the patient is referred at a time when the recurrence becomes either too widespread or develops too rapidly for further fulguration. These cases are still suitable for roentgen therapy provided the growth has not invaded too far into the bladder wall. If roentgen therapy is considered it should not be done immediately following a recent fulguration. If in a case in which fulguration has been done once or twice roentgen therapy is considered for a new recurrence the surgeon should refer this patient for radiation therapy without any further attempts to fulgurate. The necrosis following fulguration will only intensify the bladder reaction and complicate the proper conduct of therapy.

TECHNIQUE OF TREATMENT

We do not intend to discuss the technical details of the therapy but we wish to emphasize a few points which we believe have been the cause of failures in a number of our cases. The main technical errors which may lead to failure in cases primarily considered as curable lesions may be due to misjudgment of the field size in relation to the tumor or to insufficient or too rapid treatment. Led by cystoscopic examination which showed the tumor area limited to one side of the bladder we have

tried to increase the dose to this area with corresponding diminution of the dose on the contralateral portion. We have abandoned this procedure because we have observed definite progression of the tumor on the under treated side. It is probably not possible to judge exactly the limitation of the field in the bladder itself and it is necessary to include the entire bladder in the field during the whole course of treatment. Furthermore it seems necessary to treat the entire bladder in the recurrent papillary growth (the most suitable type for roentgen therapy) in order to prevent recurrences in other parts of the mucosa.

In one case we have observed recurrence of a papillary carcinoma in the lowermost portion of the trigone close to the bladder neck while the remaining bladder remained clear throughout the observation time. Since we had no other reasons to explain this localized recurrence we feel that in all likelihood it was due to an underdose in this most peripheral area of the field.

In 2 cases of our series a severe pelvic fibrosis developed undoubtedly due to overtreatment. In 1 case the bladder capacity became so reduced due to the bladder fibrosis that a transplantation of the ureters was found necessary. In this case the ureters were found dilated to about 4 times normal size and the kidney pelves dilated and infected. This patient died subsequent to transplantation. In another case the final outcome was not fatal, but such a marked rectal fibrosis developed that a regular rectal dilatation became necessary to avoid complete rectal obstruction.

These patients were treated during the early years of the use of supervoltage roentgen therapy when the danger to the deeper structures was not sufficiently appreciated. We have since then learned to avoid these severe reactions and no severe by-effects due to treatment have been observed so far in the cases observed in the last 6 years. It should be particularly pointed out that necrotic ulcers in the bladder which are at times found after treatment of uterine carcinoma have never been observed in roentgen therapy of bladder carcinoma. This indicates that they are most likely due to faulty technique in the radium application in cancers of the cervix rather than

to the external irradiation. In cases of carcinoma of the bladder which are controlled, cystoscopy usually does not show any remnant of the disease or any appreciable trace of the preceding irradiation. In most instances it is impossible for the urologist to recognize the location of the former lesion unless there is some area of atrophy or superficial scarring. In most cases the bladder mucosa appears normal unless the tumor was very extensive.

Rectal reactions of any degree of intensity likewise are not observed when the technique has been carefully controlled. Most of our patients are treated through 3 fields: one central anterior port and two oblique lateral ports centered toward the bladder. In this way the rectum receives its main irradiation through the anterior port only while most of the rectum is spared by the posterior fields. Only very occasionally we have observed even a transitory diarrhea.

We believe that the use of supervoltage roentgen therapy in the treatment of bladder carcinoma has a decisive advantage over the use of the lower voltages. It is possible to administer a tumor sterilizing dose through 3 comparatively small fields. With the lower voltage this tumor dose could be obtained only by a large number of fields because the skin of one single field would not tolerate the amount which it is possible to administer with supervoltage radiation. When the number of fields is increased each single field also must be larger because the aiming toward the bladder from any but the 3 fields mentioned is difficult and in order to include the entire bladder the field has to be fairly large. It thus necessitates a greater volume dose throughout the body quite frequently accompanied by more intense general reaction.

SUMMARY AND CONCLUSIONS

Of 68 patients with advanced carcinoma of the bladder treated between 1934 and 1950 with 800 kilovolt roentgen irradiation 10 are so far clinically well and cystoscopically without evidence of disease. Seven of these are well and have remained well for more than 4 years. The analysis of the successes and failures had led to certain tentative conclusions with regard to indications and contraindications.

tions of this procedure. We wish to emphasize that we do not consider these conclusions final but only a working basis for further investigation.

Contraindications. External roentgen therapy of the type here discussed for carcinoma of the bladder is a formidable procedure. Only patients in good general condition will support such a major procedure. Adequate bladder drainage and capacity and absence of marked infection are prerequisites for a fair trial by this method. Previous suprapubic operation particularly in the presence of any obstruction or infection constitutes an additional hazard to intense irradiation.

It is self-evident therefore that this method is not a procedure suitable for palliative purposes. Cancers inoperable because of extensive extension have not been benefited.

Indications. While increased experience during the last years has shown that our adherence to the contraindications as outlined is justified, we have somewhat modified our position with regard to the indications. The most suitable cases for radical roentgen therapy are the extensive papillary carcinomas in which infiltration cannot be demonstrated. If papillary carcinomas recur after repeated fulguration or if the surgeon feels that a certain type of carcinoma will probably recur after fulguration, roentgen therapy is indicated without further delay if it is considered at all. We mean that one should make up his mind in a particular case whether it should be treated by roentgen therapy or by some other procedure. If roentgen therapy is chosen it should not be requested as a last resort when the conditions for success have become considerably lessened by infiltration, poor general condition or associated infection.

The likelihood of cure by roentgen therapy is less marked in infiltrative growths. While there are some reports in the literature and in our own series substantiating the belief that certain infiltrative carcinomas might still be cured, we believe that the likelihood of control becomes practically nil when the bladder muscle is invaded. We cannot yet determine with certainty whether those patients who have benefited showed an infiltration of the

bladder mucosa only without true infiltration of the bladder wall but from our experience with other carcinomas it is obvious that with progressing infiltration control by roentgen therapy is correspondingly decreased. Carcinomas that have developed beyond the bladder wall and have become palpable by rectal examination are beyond cure. It must be considered that occasionally an infiltration might be apparent which may be due to accompanying inflammatory infiltration rather than true carcinomatous extension. It must also be kept in mind that the histological examination of the removed specimen may be misleading. The biopsy obtained from the periphery of the growth may not demonstrate deeper infiltrative portions of the tumor. A loop resection biopsy adequately done may give more adequate information than a biopsy taken only from the surface of the growth.

We feel therefore that a small carcinoma of a primarily infiltrating type is better handled by surgical excision if this is feasible. If the lesion is so located that a complete bladder resection is the only surgical procedure possible, interstitial irradiation preferably in the form of implantation of removable radium needles is probably superior to roentgen therapy provided the actual size of the tumor is not beyond about 3.5 centimeters in diameter.

With increasing experience we hope better to differentiate these tumors—those which are suitable for roentgen therapy from those which receive more benefit from other procedures. Progress however can be expected only by a careful selection of cases and impartial analysis of successes and failures. This can be accomplished only by close co-operation between urologist and radiotherapist.

REFLEX SYMPATHETIC DYSTROPHY

JAMES A. EVANS M.D. Boston Massachusetts

REFLEX sympathetic dystrophy is a most disabling often extremely painful malady following minor sprains ordinary fractures or in military or civil life trauma to blood vessels or nerves. The syndrome is characterized only at times by the excruciating burning pain that has given it the term 'causalgia,' hence a misnomer. Pain may be moderate mild or absent. The true diagnostic features are those disorders initiated by perversions of reflex sympathetic stimulation namely increased rubor or pallor sweating edema, atrophy of skin and spotty or even cystic atrophy of bone.

Mitchell Morehouse and Keen wrote the first brilliant description of this distressful phenomenon based on cases of gunshot wounds to nerves and blood vessels in the Civil War. Sudeck described cases of painful joint involvement giving rise to the term Sudeck's syndrome. Lenche pointed out most vividly the role of the sympathetic system in the pernicious reflex, and Horman, in his presidential address to the Massachusetts Medical Society in 1940 brilliantly described the picture and cure of several cases of minor causalgia. To Livingston in his scholarly monograph entitled *Pain Mechanisms* I would wish to give credit for the clearest theoretical elucidation of the reflex itself. In the diagram and ideas expressed in this article I have borrowed heavily from his theory to explain the vicious circle producing the syndrome of reflex sympathetic dystrophy.

MECHANISM OF REFLEX SYMPATHETIC DYSTROPHY

Figure 1 illustrates diagrammatically the nervous pathways giving rise to the syndrome of reflex sympathetic dystrophy. The fundamental concept of the internuncial pool (Fig. 2) advanced by Lorente de N6 and adopted by Livingston can be explained simply as follows. A prolonged bombardment of pain impulses sets up a vicious circle of

From the Department of Internal Medicine, The Lahey Clinic.

reflexes spreading through a pool of many neuron connections upward, downward, and even across the spinal cord, and perhaps reaching as high as the thalamus itself. Because of the summation principle of nervous impulses, there is kept alive within such a pool a constant circling of activity across the synapses involved. Some of these synapses include the sympathetic motor neuron cells in the lateral horn controlling vasomotor tone and the sweat glands. Spasm in the arteriolar and venule end of the capillary loops raises filtration pressure and edema and swelling result. Cyanosis and anoxemia increase capillary permeability and filtration further augmenting edema. Other synapses involved may be the anterior motor horn cells, giving rise to skeletal muscle cramps and spasms. Out of the pool also arise augmented stimuli to pain traveling up the thalamic tract. Depending on the wide spread of the pool we detect the phenomena of pain and sympathetic disturbances observed a long distance from the injured area in the limb and occasionally even spread to the contralateral limb. The afferent pathway is represented as the sensory nerve fibers traveling in the posterior root since according to Livingston after careful review of the evidence, pain bearing fibers do not exist in the sympathetic somatic system. Therefore, the abolition of pain by severance of the sympathetic pathway is not due directly to any blocking of afferent pain fibers but to an interruption of the efferent sympathetic pathways leading from the internuncial pool. It must be noted, however, that pain relief is not always complete and further measures must be taken, as noted in the paragraph on treatment.

ETIOLOGY

In the past 3 years I have gathered mainly from the orthopedic service the neurosurgical service and a few from the medical and surgical services of the Lahey Clinic, 33 cases of reflex sympathetic dystrophy. The exciting trauma or diseases are as follows: sprain, 9

Fig. 1 Reflex arc of sympathetic dystrophy embodying Lorente de No's theory of the "internuncial pool" (Fig. 2)

fracture, 5 thrombophlebitis, 4 poor foot statics, 3, bruise, 2 amputation, 2 scalenus syndrome (?), 2 laceration of hand, 1 anterior poliomyelitis (?), 1, planter wart, 1 gonorrheal arthritis, 1 thalamic syndrome (cerebrovascular accident), 1. In addition there were the complications of fungus infection in 3 and operative interference in 3. Mindful of conceiving of these cases as reflex sympathetic dystrophy and not necessarily causalgia, I have included cases which showed undoubted sympathetic vascular or sweating phenomena and only incidentally pain. This concept has led me to include 4 cases of thrombophlebitis. Injury to blood vessels in the form of arterial injury has been reported before as a cause for causalgia (Homans, Weir Mitchell, and associates). Thrombophlebitis is less often recognized as a possible source of causalgia. In 3 of the 4 cases of thrombophlebitis muscle cramps have been an outstanding feature of the pain. One of these 3 patients had no constant pain but only cramps. One patient with reflex sympathetic dystrophy with a history of 'torn ligaments' in the wrist 10 months before and

operative interference 4 months later had no pain but the sympathetic phenomena of rubor, swelling and hyperhidrosis were present to a marked degree.

Injuries in the form of sprain, fracture, bruise, lacerations and amputations together accounted for 59 per cent of the cases. Three of the patients suffered from poor foot statics; the respective diagnoses being pronated feet, relaxed feet with metatarsalgia, and pes planus.

Two cases of scalenus syndrome (unproved by operation) are included because the scalenus pressure had produced Raynaud's syn-

TABLE V—RESUME OF 32 CASES

Case Admission Date	Original injury	Pain	Trigger points	Rubber band	Pulse	Swelling	Red- ness	Altruity muscle	Roos	Crimp	Block	Sympathetic
1-30-44	Anterior poliomyelitis at 3	Extremes, 18 yrs. Causalgia.	+	++	+	++	-	-	-	-	Relief	90% improved in 37 mos.
4-16-44	Spindle 9 mos. before	Mild 9 mos.		+	-	+	-	+	(Method)	-	Relief	90% improvement by 3-4 mos. later atrophy
7-1-44	Fracture of metatarsal 4 approx. 100% interval of causalgia	Severe, 6 mos.	+	+	+	-	-	-	(Method)	-	Relief with trigger point gone	3 wks. relief of causalgia but pain persists from causalgia myelitis in ad metatarsal
8-1-44	Pes planus	Moderate, 6 mos.	-	-	-	+	-	-	(Blanchy)	-	100% relief mo. (proper shoes alone)	
8-1-44	Concussion arthralgia 3 yrs. ago by fall from 10 ft. followed by fracture fibula; causalgia type	Swelling over rt. leg and 3 yrs. Causalgia.		+	+	++	-	-	+ surgical excision rt. leg	-		Sympathetic for 3 yrs. particular 100% relief of pain 3 mos. later
8-7-44	Posterior thrombophlebitis 3 yrs. after venogram positive	Moderate, 6 yrs. 1 severe, yrs.	+	-	-	-	-	-	-	-	3 wks. post- operative relief of trigger point	
9-7-44	March fracture of tibia; phle- bitis of thrombophlebitis in ex- posed venogram; causalgia type	Moderate, 9 mos.	+	+	+	+	-	-	-	-	97% relief on 3 blocks remained better of result of surgical trigger point gone	Sympathetic, re- mained better of result of surgical trigger point blocks in not permanent
9-7-44	Leucostoma across rt. heel 37 days later operation on heel	Causalgia severe yrs.	+		+	+	+	+	+	-	No relief	90% relief 3 mos. (sends sends phlebotomy and injections of trigger points)
9-8-44	Plaster cast	Acute, 9 mos. Causalgia.	+	+	+	+	-	-	-	-	Recommended	
10-8-44	Fracture of radius	Severe, yrs.	+	+	+	+	+	+	+	-	Relief	Marked days
6-1-44	Squarish thrombophlebitis in varicose vein	Severe	+	+		+	-	-	-	++	Blocks, 3 (small) 97% relief yrs.	
11-7-44	Fractured foot	Moderate	-	-	-	-	-	-	-	-	Relief 90%	
12-8-44	Refracted nail	Moderate	+	-	+	+	-	+	(Radio- log)	-		9 mos. 5% improvement sends injections of trigger points and phlebotomy
12-8-44	Old thrombophlebitis	-	-	+	-	+	-	-	-	++	Recommended	
9-9-44	Spindle yrs. ago; trigger point	Severe, yrs.	-	+	-	++	+	-	+	-	Relief	mos. 95% improvement
9-12-44	Two hematomas in right 10 mos. one operative; other in mos. ago	-	-	+	-	+	-	-	+	-	Recommended; better by further opera- tion procedure	

drome together with constant pain, relieved by cervical sympathetic procaine block.

In one case a plantar wart gave rise to excruciating pain in the foot associated with rubor and swelling of 9 months duration.

A patient who had had gonorrheal arthritis of the foot 8 years before retained a swollen sore big toe for 8 years. Roentgenogram of the toe demonstrated an aseptic necrosis and physical examination revealed rubor, swelling and hyperhidrosis associated with fungoid ulcers. Severance of the lumbar sympathetics abolished pain and led to healing of the ulcers after abolition of the excessive sweating.

One patient with thalamic syndrome who had hemiparesis following a cerebrovascular accident experienced temporary relief of causalgic pain in her right arm after cervical sympathetic block with procaine. This surprising result might arouse much speculation on the mechanism of so called thalamic pain. Opportunities to repeat this observation are needed.

A single case is reported here of terrific causalgic pain for 25 years that may have followed infantile paralysis at the age of five.

Local operative interference may only exacerbate the reflex sympathetic dystrophy already well established, as occurred in 3 cases. In such cases sympathectomy is advisable before the necessary local surgical procedure is attempted. Fungus complications in the fertile soil created by hyperhidrosis seemed to increase the severity of the symptoms in 3 cases.

PAIN

Pain is usually the most prominent feature in reflex sympathetic dystrophy. It may be one of the most excruciating pains human flesh is heir to: a deep burning agony throughout an entire foot, hand or limb that makes a patient wince as one approaches him with the examining hand; a pain that sometimes makes him contemplate suicide. Trigger points are often multiple and pressure on one often spreads a diffuse pain of a burning peculiar nature up and down the limb. More often in less severe cases the pain response stays definitely localized to the trigger point. In our 32 cases, trigger points, single or multiple were found in 19. Pain was excruciating and of a burning causalgic nature in 5 rated

severe in 12, moderate in 11, mild in 2 and none existed in 2 cases. These last two patients showed other signs of reflex sympathetic dystrophy.

OTHER SYMPTOMS AND SIGNS

Rubor was present in 15 and pallor in 9 cases. The rubor may be so constant and the foot or hand be so hot that the picture of erythromelalgia is produced. Livingston has suggested that rubor is often present in early cases, pallor in the more chronic cases. This has not been my impression in this series. In 6 cases rubor was present and of 2 years' duration or more and in 1 case for as long as 18 years. Swelling or sweating or both was present in over half of the cases. Atrophy of the skin was noted in 4 and of muscle in 7 patients. The typical bone atrophy of sympathetic origin is mottled. In advanced cases even cystic, presumably owing to nutrient artery spasm. Such bone atrophy was described in the roentgenograms of 6 patients in this series. A diffuse osteoporosis resembling that of disuse was noted in 5 cases. Trigger points were noted in 19 cases.

DIAGNOSIS

Either cervical or paralumbar sympathetic procaine block comprises a diagnostic therapeutic test. The relief of pain may be almost miraculous but need not be so dramatic as to establish the diagnosis provided relief of other phenomena is also noted, such as relief of sweating, increased warmth and comfort, a cold member associated with rise of skin temperature (temperature index test) and disappearance of trigger points. Nineteen of our 32 patients had blocks performed with varying amounts of relief in all but one.

TREATMENT

The ideal point of attack would be the international pool itself. So far no direct effective means is at hand to stop the vicious circle within this pool of neuron synapses.

Two other points of attack exist: the trigger points and the sympathetic pathway. Repeated injections of the trigger points usually are necessary. If the sympathetic pathway is blocked by procaine, one is occasionally gratified

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 4. Case 2. Mottled bone atrophy of reflex sympathetic dystrophy (Sudeck's syndrome).

Fig. 5. Case 3. Marked mottled type of bone atrophy.

Fig. 6. Case 5. Gonorrheal arthritis 8 years before ad

mission. No evidence of gonorrheal activity at present. Aseptic necrosis of both phalanges of right great toe, diffuse osteoporosis of distal radius. Condition was cured by splanchnicectomy.

fed by the astounding relief obtained with only one injection. More often there are lapses within a few days or weeks and repeated injections are necessary at longer and longer intervals. It would seem more logical to give a series of three injections one every second day for more permanent rupture of the pernicious reflex, a method so successfully applied to thrombophlebitis (Fig. 3).

At the clinic we have felt it best to resort to sympathectomy in the majority of our treated cases after the demonstration of the efficacy of one block in order to obtain the maximum of relief and the greatest assurance of permanency of relief.

Posterior root rhizotomy, cordotomy or for high cervical segment interruption of the thalamic pathways in the medulla and even resection of the sensory cortex may be necessary in exceptional cases.

Nineteen patients received sympathetic procaine block with varying amounts of relief of pain and sympathetic phenomena in all but one. Nine patients were treated by block alone. Of these 9, 7 had 50 to 100 per cent

relief of pain for 3 weeks to permanent relief. Two of the 9 received only temporary relief for the duration of the procaine effect. Only 1 patient was treated by injection of trigger points as well as by sympathetic procaine block, with relief of pain for only 3 weeks. A sympathectomy is to be done on this patient. Thirteen patients have had sympathectomy with pain relief ranging from 75 to 100 per cent in 9 (69 per cent). Failure to 25 per cent relief resulted in 4 of the 13 cases.

ILLUSTRATIVE CASE REPORTS

CASE 1. A woman aged 30 years came to the clinic November 20, 1913, because of extreme caustalgic type of pain in the right leg for 25 years following an attack of what may have been anterior poliomyelitis at the age of 5 years. There was marked rubor, moderate swelling and marked sweating and several trigger points were present. The pain was so extreme that she had developed a conditioned reflex with the hands breaking out into sweat if one made a motion toward her foot as though to touch it. She took a half hour in the morning to put her shoes on because her right foot was so tender.

Paravertebral sympathetic block afforded marked temporary relief. Sympathectomy was performed.

Fig. 7

Fig. 7. Case 6. Thrombophlebitis of 8 years' duration. Venogram showing no filling of deep venous circulation.

Fig. 8

Fig. 8. Case 7. Callus of old "march fracture"

with 90 per cent relief of pain and 100 per cent relief of rubor swelling and excessive sweating when the patient was seen 1 year and 10 months later. There was still slight tenderness over the trigger points behind the external malleolus below the lateral aspect of the right knee. The patient was most grateful.

CASE 2. A woman came to the clinic February 16, 1944 because of mild pain, rubor swelling and slight muscle atrophy which had been present ever since she sprained her ankle 9 months before admission. The roentgenogram showed mottled bone atrophy (Fig. 4). Paravertebral sympathetic block afforded temporary relief. Sympathectomy was done with 90 per cent relief of pain in 1 month. At this same time a roentgenogram showed less bone atrophy.

CASE 3. A man had sustained a fracture of the second metatarsal followed by operative removal of exostosis 6 months before admission to the clinic, October 8, 1944. For the past 6 months there had been severe pain in the foot. Trigger points, rubor swelling and bone atrophy were present (Fig. 5). Paravertebral sympathetic block afforded relief with disappearance of trigger points. Sympathectomy was done and after 3 weeks there was relief of the causalgic pain. However pain was still persistent in the foot from the osteomyelitis of the second metatarsal. A colored photograph 3 weeks after operation showed definitely less rubor and swelling.

CASE 4. A man came to the clinic August 14, 1944 because of moderate pain in the right foot of 6 months duration. There was definite swelling and a blotchy type of bone atrophy. There was no history of trauma but marked pes planus was present. One month after one paravertebral block, 100 per cent relief of pain was obtained. The patient also had proper shoes fitted.

CASE 5. This man came to the clinic June 13, 1944. He had suffered from gonorrheal arthritis 8 years before admission. There had never been complete subsidence of pain in his right big toe and foot. Hy perhidrosis had been present, complicated by fungus infection, with ulceration. Rubor swelling, and marked sweating were apparent. A roentgenogram showed an aseptic necrosis in the toe (Fig. 6). The patient also had essential hypertension. For this reason a splanchicectomy rather than sympathectomy was done. There was 100 per cent relief of the pain in the right foot and toe. Three months later his foot was dry and the ulcers had healed. A check-up roentgenogram of the toe showed the same aseptic necrosis present.

CASE 6. A woman came to the clinic August 7, 1944. She had suffered postpartum thrombophlebitis 8 years before admission. For the last 6 years there had been moderate pain, which had grown much more severe during the last 3 years. A trigger point was present over the popliteal vessels. A veno-

gram (Fig. 7 a and b) showed failure of deep venous filling in the calf and thigh. A paravertebral sympathetic block afforded 100 per cent relief for 3 weeks following which there was a relapse. It is planned to inject the trigger point and repeat the paravertebral block.

CASE 7. A college girl aged 21 years came to the clinic September 7, 1944. She had suffered moderate pain in the right lower leg following a fall skating 9 months before admission. Marked swelling and rubor developed. For the past 2 months purpuric spots had appeared over the right lower leg. Sweating had become pronounced. Soon after the fall she was confined to bed with what was called the flu. At this time she had fever and red streaks on her leg. A venogram at the time of her hospital entry showed normal filling of the deep calf veins and the femoral vein in the thigh. There was normal capillary fragility in the affected leg. Coagulation time, bleeding time and platelets were normal. A roentgenogram of the tibia revealed the callus of an old "march fracture" (Fig. 8).

This patient was treated with a series of three paravertebral sympathetic procaine blocks in 1 week. At the end of the week the swelling had subsided and the trigger points had disappeared. She was seen 3 months later and pain was completely relieved.

CASE 8. A woman had sustained a laceration on the dorsum of the right hand a year before being seen at the clinic, September 7, 1944. Two operations had been performed on the hand in the hope of relieving severe causalgic pain of a year's duration. Trigger points, pallor, sweating and muscle atrophy were present. Roentgenograms demonstrated diffuse bone atrophy. Paravertebral block afforded no relief. Nevertheless sympathectomy was done, with 50 per cent relief of pain 3 months later. This patient needs much physical therapy which it is now possible to give because the limb is so much less tender to manipulation. Injections of trigger points are advised.

CASE 9. A man came to the clinic, June 28, 1944 because of a plantar wart with excruciating pain through the foot for 9 months. A trigger point was present over the wart. Rubor and swelling of the foot were noted. Paravertebral sympathetic block was recommended but refused.

SUMMARY

Reflex sympathetic dystrophy is described as a syndrome produced often by minor trauma or disease in a limb leading to the reflex production of the sympathetic phenomena of rubor or pallor, heat or cold, increased sweating, edema and pain. Since the factor of pain

may be absent, the term reflex sympathetic dystrophy is preferred to causalgia.

The rôle of Lorente de Nó's "internuncial pool" in the production of the syndrome of reflex sympathetic dystrophy is presented.

Traumatic injury accounted for only 59 per cent of the 32 cases reported.

The typical bone atrophy of reflex sympathetic dystrophy is mottled or cystic (Sudeck's syndrome).

Diagnosis depends largely on the demonstration of relief by sympathetic procaine block. Nineteen of the 32 patients received sympathetic block with procaine, with varying amounts of relief of pain and sympathetic phenomena in all but 1 patient.

Treatment may be directed to blocking the trigger points if they exist and to blocking the sympathetic pathway. In 9 patients treated by sympathetic procaine block alone, 7 had relief of pain varying from 3 weeks to permanent; such pain relief estimated at 50 to 100 per cent. The other 2 received relief of pain only for the duration of the procaine effect.

Thirteen patients of the 32 here reported had sympathectomy performed with relief of pain ranging from 75 to 100 per cent in 9 or 69 per cent. Failure to 25 per cent relief of pain resulted in 4 of the 13. The 2 patients who had no pain but other sympathetic phenomena have so far not submitted to either block or sympathectomy.

A SINGLE STAGE OPERATIVE METHOD OF MANAGEMENT OF CHRONICALLY INFECTED UNUNITED FRACTURES

FRED G. HICKS, M.D. F.A.C.S. Quebec, Canada

COMPOUND fractures of the long bones are seen relatively frequently among war casualties particularly favored for this injury are both bones of the leg. Unfortunately a rather high percentage of these cases become infected and later present the picture of chronic osteomyelitis or soft tissue infection and nonunion. Review of statistics reveals that there has been an increase in the incidence of faulty union during this war seen in both simple and compound cases in spite of the use of the sulfonamides and penicillin. In a good number of cases treatment was delayed by transport difficulties others were wounded previous to routine use of the drugs.

In the far past, because of a long line of unhappy experiences a markedly conservative restriction was placed upon surgical interference in cases with infection. Operation was mentioned only to be condemned. Recently since the advent of the chemotherapeutic agents which render the infecting organisms avirulent practice has been to administer preliminary supportive and specific therapy then at operation to excise the infected tissues as thoroughly as possible and secure drainage. After subsidence of the infection a grafting operation is performed. This accepted procedure has been and still is for certain cases the one practiced here. However a number of protracted convalescent periods while cure of the infected area was awaited and one case of relighting of a latent infection some months after bone grafting caused a different procedure to be adopted with a certain type of patient.

Particular concern was shown over cases with marked loss of bone substance and ones with lengthy infection. In these instances in view of the extensive fibrosis of soft tissues

with marked sclerosis and atrophy of the main fragment ends, it seemed that the preliminary operation for excision and drainage could not possibly remove all the factors of latent infection to prepare for grafting. The length of convalescence before rehabilitation could begin was not in the best interest of the patient's mental outlook and general health equally important. It endangered the preservation of function of the limb involved. This latter factor was of most serious import, as the prolonged immobilization would lead to irreparable contracture and fibrosis of the musculature and periarticular structures, resulting in partial or complete permanent disability of the limbs. A resultant united fracture in a limb with stiff or painful joints would leave much to be desired. In patients with long standing osteomyelitis and moderate-sized bony defects, we believed that a departure from previous practice might be made before amputation was considered.

A group of patients was chosen for more radical procedure. Eleven cases with long bone involvement are illustrated below similar circumstances have been successfully treated in small bones. The patients were adults in the various armed services who received compound fractures in the line of duty with subsequent infection. All infections were in the quiescent state when treatment was begun. Some patients revealed frank osteomyelitis while others suffered from chronic infection of soft tissues, with or without dispersed small bone fragments. Most of the patients showed a flail-type of nonunion plainly evident at physical examination. The technique of the single-stage procedure upon leg cases, consisting simply of a radical osteotomy and excision of infected soft tissue with internal fixation by plating will be given in outline to avoid repetition.

From Ste. Anne Military Hospital, Ste. Anne de Bellevue.

Fig 1 Case 1 a, Preoperative views b 1 day post operative c, 8 weeks postoperative showing the usual

absorption and bone regeneration d 1 year post operative.

PRELIMINARY PROCEDURE

1 Roentgenological investigation is made of the involved bones and adjacent joints. Sinuses are injected with radio-opaque material to determine recesses location of foreign material and such conditions

2 General condition is investigated thoroughly and an intensive therapeutic period is instituted with bed rest this includes frequent whole blood and plasma transfusions high protein and vitamin intake (vitamin C is stressed)

3 Sulfathiazole is given orally to maintain a blood level of 5 milligrams per cent

4 In several instances dictated by investigation other medication such as thyroid extract, is instituted

5 Mild physiotherapy in form of gentle massage and movement is applied to the adjacent muscles and joints. No specific treatment of the local condition is adopted other than adequate splinting and the usual cleansing of sinus regions by shaving compresses, or dry dressings. For 12 hours previous to operation alcohol dressings are applied

The length of this treatment depends upon the degree of general depletion of each patient and the local skin condition in most instances the skin is severely crusted and granular from lengthy closed plaster therapy

OPERATION

After skin preparation of the whole limb a generous longitudinal incision allowing wide

exposure without tension on the skin is made. The incision includes encircling of sinus openings and is placed 2 inches medial or lateral to the anterior tibial crest. The incision is deepened to expose the tibial periosteum. If possible without sacrifice of the closure all skin scar is excised at this time. However at times the excision of noninfected skin scar is delayed for a future plastic operation. Pains are taken not to traumatize the skin edges. Sinus tracts and all devitalized tissues are excised completely. Loose bony fragments are removed but fragments which are deeply embedded, far from the fracture site and which have no apparent connecting tract are not disturbed. The tibial periosteum over healthy bone is split and reflected about the whole circumference in most instances it is absent or replaced by scar over the infected region. After the tibia has been separated from its bed the two main fragments are usually separated transversely by scalpel. At times the central block of eburnated bone and infected granulation tissue are removed *en masse* by saw but in the majority of cases to allow resection of the bone at the proper levels, the former measure has to be taken. The amount of the main fragments to be removed is more or less predetermined by x ray evidence of the extent and degree of bone sclerosis. The ends of the bones are sawed squarely across to expose freely bleeding marrow canals circumscribed by healthy cortex free of infected granulations. No heed is

Fig. 2. Case 2. a, Preoperative views, b, 3 months postoperative, c, 5 months postoperative, d, 7 months postoperative.

paid at this time to length conservation the minimal requirement is that the segments to be approximated be viable. With such an increased exposure the soft tissue bed of the fracture site, consisting of dense scar interspersed by small pockets of granulation tissue are thoroughly excised care being taken to preserve main arterial and nerve trunks. It is then necessary similarly to expose the fibular fracture site through separate or the same incision and accord it the treatment described. If the fibula has not been fractured, or more commonly if it has healed without infection an equal length of its shaft is excised by saw occasionally it is cut across obliquely to allow its fragments to override without removal of a portion. If the tibia is markedly porotic, the fibula is transected low down so that the superior fragment crosses the tibial fracture to be incorporated in that bone for added strength. The main tibial fragments are then accurately approximated in proper alignment and maintained so by an 8-screw vitalium plate. The plate is applied to the anterior surface of the tibia opposite to the incision site e.g. if the incision is necessarily anteromedial the plate is fixated to the anterolateral tibial surface. (As in fresh-fracture plating certain principles are helpful (a) the plates used are long (b) the screws are

placed eccentrically for added purchase, (c) the screws penetrate the opposite cortex, (d) if wire is used it is of the same metal). The wound is then thoroughly irrigated with normal saline and dusted with sulfathiazole powder. The skin and subcutaneous flaps are closed if possible in a single layer of silk mattress sutures no catgut is buried. If much skin has been lost the closure is difficult or impossible even after wide undercutting of the flaps. In the event of incomplete closure the edges are approximated as well as possible and vaseline dressings are applied without any form of skin-grafting. A moderate pressure dressing with cotton waste follows. The limb is enclosed in plaster from upper thigh to toes with ankle at right angles and knee in 10 degrees flexion. A long window is cut over the incision but it is left unopened.

These principles of technique are similar in the thigh and upper limb fractures, differing only in size of plate, and approach. Spinal anesthesia is used for all lower limb cases cyclopropane and oxygen are chosen for those of the upper limb. All patients receive whole blood or plasma transfusion during operation.

POSTOPERATIVE

The preoperative regimen outlined is resumed. In most instances the sulfonamides

Fig. 3 Case 3 a, Preoperative views, b immediate postoperative views. Note that the screws could not be used in lower fragment due to marked osteoporosis. c, Twelve months postoperative. Plate was previously removed at tendinoplasty

are discontinued in the second week. The wound is inspected on the sixth day through the window and if there is any sign of infection several central sutures are removed and warm saline compresses are applied. Otherwise, all sutures are removed on the ninth day. A walking plaster cast extending from the knee is applied in 5 to 6 weeks and remains present until end of third month.

ILLUSTRATIVE CASES

CASE 1. An infantryman received an explosion wound and was operated upon here 17 months following trauma. Examination revealed a compound fracture of both bones of leg with skin defect and discharging sinus from nonunion infected tibial fracture. The fibula was partially healed by fibrosis. Following operation, the wound healed completely. The use of walking caliper splints was begun in sixth postoperative week. Patient was walking without any support 12 weeks postoperatively with moderate evening ankle swelling. There were no signs or symptoms for 3 years postoperatively. Total limb shortening was $1\frac{3}{4}$ inches (Fig. 1).

CASE 2. Patient was injured in a plane crash, and was operated upon here 11 months following original surgery. He also suffered fracture of other leg and skull. Examination revealed compound fracture of both bones with nonunion, very profuse purulent discharge with skin defect and projecting bone plate, osteomyelitis of tibial fragments only. Following operation, slight serous discharge continued only 10 days through the skin defect. Wound

was completely healed in 4 weeks. Walking by caliper splints was begun in fifth postoperative week. Patient was walking very freely without support by twelfth postoperative week. He was accepted for duty in Merchant Navy 8 months after operation. He had no complaints 2 years after operation. Total shortening of limb was 1 inch (Fig. 2).

CASE 3. Patient was injured in a mortar explosion. He was operated upon here 14 months following wound. Examination revealed a compound fracture of both bones with nonunion, chronic osteomyelitis and sequestration at both tibia and fibula fracture sites, tibialis anticus and extensors all destroyed, moderate skin defect. There was a moderate amount of purulent discharge from the wound. After operation the wound healed completely. Walking by caliper splints was begun 6 weeks after operation. Patient was walking with no support to leg but foot straps in 15 weeks. There was no evidence of infection, etc. 2 years following operation. Function was restored by tendinoplasty. Total shortening was $1\frac{3}{4}$ inches (Fig. 3).

CASE 4. Patient was injured in a plane crash. He also sustained fracture of pelvis and hip dislocation. He was operated upon here 3 months following trauma. Examination revealed a compound fracture of the tibia with grossly infected fragment ends, fibular fracture not infected. There was no sign of attempt at union and a discharging skin sinus was present. The wound healed after operation by primary intention. Walking by caliper splints was begun in 8 weeks. Its application was delayed by other fractures. Walking without support was possible in sixteenth week and he was returned to duty. Total shortening $\frac{3}{4}$ of an inch. No disability for past 2 years (Fig. 4).

Fig. 4. Case 4. a, Preoperative view; b, Immediate postoperative view —note lower leg fractures also; c, 6 months postoperative.

CASE 5 Patient was injured in a motor accident. One sequestrectomy had been performed. He was operated upon here 6 months later for flail limb with discharging sinus. Examination revealed nonunion with chronic infection of tibia and sequestration. Osteotomy of both bones was performed. The wounds healed without complication. Walking cast was applied in 5 weeks; he was walking without support 3 months after operation. Total shortening was 1 inch. Elective removal of plate 2 years later revealed perfect union without evidence of infection. Full duty performed during the past 2 years without symptoms (Fig 5).

CASE 6 Patient was injured in a plane crash and suffered compound fracture of both bones with ulcerated discharging wound and flail-limb. Operation was performed here 5 months following accident. Examination revealed nonunion with sequestra and

small loculations of pus about the tibial fragment. The lower fragment was markedly osteoporotic. Following the osteotomy, the upper fibular fracture was placed across the tibial fracture. The wound healed completely. A walking cast was applied in fifth week and all splinting was removed after 3 months. Patient was on full flying-duty 7 months after operation. Total shortening was 1 inch. Plate was removed for inspection 1 year later; no residual infection was evident. He has had no complaints for past 2 years. (Fig 6).

CASE 7 This case is presented for comparison. Patient was injured in a motor crash. He also suffered a fractured spine. He had had a series of previous sequestrectomy operations. Operation was performed here 2 years following injury. The findings were compound nonunion flail-fracture of tibia with osteomyelitis and sequestration; fibular

Fig. 5. Case 5. a, Preoperative; b, 1 month postoperative; c, 1 year postoperative.

Fig 6 Case 6 a, Preoperative views b 5 weeks postoperative c, 1 year postoperative.

fragments partially united and not infected. Also profuse discharge through multiple skin sinuses. In this case the usual osteotomy was not performed due to extensive sclerosis of large intermediate tibial fragment. The necrosed bone and infected soft tissues were thoroughly excised plate was applied for stability. The wound healed primarily one month postoperative a single small sinus formed and intermittently recurred for 1½ years but discharged only spots of thin serum. Bone union progressed slowly. Patient walked without support in twelfth postoperative week. No shortening. Plate removed recently and bone was seen to be healed securely.

CASE 8 Patient was injured in a plane crash. He suffered compound fractures of both femora. Both bones were plated. The right femur united firmly with marked lateral bowing. The left femur was infected and nonunited. He was operated upon here 8½ months later. The findings were flail limb with gross infection of fragments sequestration, and discharging sinuses. Considerable pus and marked loss of bone substance were noted. bone plate was very loose. The plate was removed and an osteotomy and plating were performed wires were also used because of marked osteoporosis. Patient refused splin and only posterior thigh mold was used. The wound discharged small amount of thin pus for

Fig 7 Case a, Preoperative view b, Two months postoperative c, Six months postoperative

Fig. 8. Case 8. a, Preoperative view b, 5½ months after operation. No evidence of infection about the screws. Usual changes for this period at osteotomy site.

3 weeks then healed completely. An ischium-bearing walking caliper with crutches was allowed 6 months after operation. Patient refused further plastic bone repair and was transferred. When re-examined 1 year later he was walking with a cane but no recurrence of infection was evident. Limb shortening was not significant as the opposite femoral bowing compensated (Fig 8.)

CASE 9. Patient was injured in a motorcycle accident. He received a compound fracture of the middle third and simple fracture of metaphysis of left femur. The upper fracture failed to unite the

lower one healed. Operation was performed 9 months after accident. The findings were No discharging sinuses were noted but sequestra and burrowing pus pockets about fragment. Plate was placed anteriorly away from skin incision. The wound healed completely. Posterior body leg cast was maintained 2 months. A walking caliper splint was applied at 3 months and patient was able to return to college. The plate was removed for inspection 11 months later. He has had no complaint for past 16 months. Total shortening was 1¾ inches. (Fig 9.)

CASE 10. Patient was injured in a motor accident. Two subsequent sequestrectomy operations had been performed. He was operated upon here 5 months following accident. The findings were compound fractures of both bones with distal radial fragment extruding and chronic infection of fragments of radius and of soft tissues. Flail limb. After osteotomy of radius and excision of infected granulations, the ulna was shortened through a separate incision. Following operation, the wound healed completely. The cast was removed after 6 weeks. Total shortening was ¾ of an inch. Functional return was complete. He has had no disabilities for past 12 months. Patient returned to duty as coal stoker (Fig 10.)

CASE 11. Patient was injured in a motor crash. Compound fractures had been openly reduced. He was operated upon here 4 months after accident. The findings were Compound fractures of both bones of forearm with flail nonunion. Chronic infection of fragment ends with small sequestra and wire through ulna sinus over dorsum of ulna. Following operation the wounds healed completely. Splinting was substituted by sling in 4 weeks. All movements were complete. Plates were removed 4 months after operation without signs of infection.

Fig. 9. Case 9. a, Preoperative views b, 1 day postoperative c, 11 months postoperative

Fig 10. Case 10. a, Preoperative views b Two and one half months postoperative c, One year postoperative.

Three years have passed without disability. Total shortening was $\frac{3}{4}$ of an inch (Fig 11)

OBSERVATIONS

This is not an established method of treatment and will undoubtedly be the subject of considerable diversion of opinion. Although exceptionally good fortune attended the patients, precisely the same sequence of events was noted in the clinical and x ray progress toward secure union without undesirable sequelae in no instance has there been oc-

casión to regret the procedure. It did not seem that a lack of bone-forming capacity existed once the grossly infected sequestra and soft tissues had been removed and vascular bone fragments were properly immobilized in apposition.

Without embarking upon discussion as to the etiological factor in the nonunion in these cases beyond the common one infection histories indicated that interrupted skeletal traction had most commonly occurred. In adequate fixation which is the expected

Fig 11. Case 11. a, Preoperative views b, Three months postoperative c Six months postoperative

accompaniment of mobile war plus a low vitamin C intake were strikingly constant.

While for the most part the ages of the patients were below 35 years, others represented the fourth and fifth decades.

The infection unlike blood borne osteomyelitis, was limited to the fragment ends and to surrounding soft tissues containing smaller loose bone and therefore afforded opportunity for excision. The marked bony eburnation and surrounding avascular fibrosis inhibited elimination of infection solely by chemotherapeutic measures. Organisms were mixed with staphylococci predominating accompanied by streptococci saprophytic organisms, *Bacillus pyocyaneus*, and rarely *Bacillus coli*.

In no instance was there evidence of post operative dissemination of the infective organisms, or a tendency toward local spread.

Importance of local or general administration of chemotherapy must not be overstressed in several of the most grossly infected cases use of drugs was omitted totally because of previously determined allergy.

There have been no residual sinuses or other unfavorable sequelae in those cases in which the full procedure could be performed. Case 7 is given as example of failure to eliminate completely infection in an instance in which an extensive osteotomy could not be done. Osteogenesis was very slow and the bone spanning the infected area appeared sclerosed and brittle. The plate remained firm and maintained immobility during the lengthy healing period. Case 8 primarily very grossly infected eliminated the infection very quickly and united in spite of small surfaces of bone apposed. In this instance the procedure quickly afforded the abandonment of skeletal traction and eliminated the external reinfection of the wound. This latter factor is considered to be an important accomplishment of this procedure.

Postoperative pain was noted by its absence.

From x ray and later operative examination there is reason to believe that the enclosed metal does not form a formidable nidus for bacterial growth. Alarm that plates maintain the fragment ends in dis-

traction during the early physiological period of resorption resulting in non union is not justified by serial roentgenograms in the cases reported here given time firm union occurred. While the plates merely act as splints they can be credited with allowing security over the increased fragility period of bone healing and they allow considerably earlier movement of adjacent joints. (Particularly the ankle and foot.)

Several plates were removed to allow examination of the local area to verify complete absence of latent infection. The screw holes did not fail to heal. Operation for plate removal in these cases is deemed unnecessary.

It will be noted that some bone loss occurred at the original injury the operation further subtracted from the limb but the average total loss in length was 1 inch and did not exceed $1\frac{3}{4}$ inches. It must be remembered that a certain amount of length loss is also an accompaniment of a simple bone grafting procedure in such cases, if the sclerosed bone ends are carefully resected. The shortening in this small series was compensated by the wearing of shoe-lifts which proved to be comfortable and non-disabling. The lower limb cases have been free of complaints, and follow up observation of their backs and pelvis fails to elicit distortion of normal alignment.

SUMMARY

1 A single stage operative method of management of chronically infected fractures with nonunion is considered.

2 The procedure which is performed during the quiescent stage, consists of an exacting excision of infected tissues to create a new vascular bed followed by plate fixation for immobilization.

3 The progress of bone and soft tissue healing is favorably comparable to fresh fracture healing.

4 Cessation of local infection and absence of dissemination are noted the factor of latent infection is negligible.

5 The limb shortening is minimal and is compatible with normal activity and comfort.

6 The procedure hastens local and general rehabilitation and helps patients morale.

THE SAPHENOUS VENOUS TRIBUTARIES AND RELATED STRUCTURES IN RELATION TO THE TECHNIQUE OF HIGH LIGATION

Based chiefly upon a study of 550 anatomical dissections

EDWARD H. DASELER, M.D. BARRY J. ANSON, Ph.D. (Med. Sci.),
ARTHUR F. REIMANN, M.D. and LINDSAY E. BEATON, M.D. Chicago, Illinois

RECENT medical literature contains many articles on the treatment of varicosities of the veins of the lower extremity. However little has been written about the tributaries of the upper portion of the great saphenous vein or about related fascial structures. Since attention is necessarily focused upon this area in the treatment of varicosities, knowledge of the commoner types of venous patterns and of variations in form and size of the fossa ovalis should be of service to the surgeon.

The present account deals with vascular varieties to include the following superficial veins: iliac circumflex, external pudendal, epigastric, lateral and medial accessory saphenous veins. In addition the observations have to do with the fossa ovalis and its contained femoral vessels, with the overlying and surrounding fascial layers and with some recommended features of surgical technique which are in the main based upon the anatomical aspects of the study.

MATERIAL AND METHODS

All anatomical observations were made on dissection room specimens (American whites and negroes, preponderantly male). The observations on fascial layers were made concurrently with those on the blood vessels, covering 350 consecutive body halves. The statements on form and size of the fossa ovalis and on the relations of the femoral vessels are taken from an earlier investigation covering 200 consecutive lower extremities (Anson and McVay, 1938); those on structure of the femoral sheath are based upon a study of the

anatomy of femoral hernia (in preparation, Anson, Ashley, Reimann and Beaton).

A sketch of the subcutaneous veins of the inguino-femoral region in each of the 350 thighs was prepared. Accessory venous tributaries entering the great saphenous vein more than 6 centimeters below the junction with the femoral were not considered. In selecting the anatomic types of venous convergence upon the main saphenous vessel, those records represented the specimens types therefore were not selected early in the study from a limited group and then set up as categories into which later cases were fitted.

The illustrations in Figure 2 are diagrammatic, the distance between tributaries and the caliber of the latter being arbitrary. Those in Figures 1, 3 and 4 represent actual specimens. The illustrations in Figure 5 are based upon e and g of Figure 3; ligatures are placed at points which, in the experience of the senior author, would have been selected in actual surgery of the case.

OBSERVATIONS AND DISCUSSION

1. ANATOMY

The anatomical material will be presented in the order in which the sets of layers or groups of vessels are encountered in dissection: first will be considered the superficial fascia, next the superficial veins, finally the deep fascia with its fossa ovalis and the contained femoral vessels.

a. Superficial fascia. Over the proximal third of the thigh, in the area of the femoral triangle, the superficial fascia is two-layered, just as it regularly is in the adjacent inguinal and perineal regions (McVay and Anson, 1938 and 1940). The outer superficial layer

of the bilaminar superficial fascia is a fatty stratum, while the inner deep layer is fibrous the latter contributes to the formation of a strong membranous investment for the larger vessels of the thigh. It is rather readily separable from the outer adipose layer (Fig. 1 a and b). In addition to the superficial veins the subinguinal and inguinal lymph glands are situated in this deep membranous stratum which, in the femoral triangle some times contains an appreciable deposit of fat. When followed into the fossa ovalis, and therefrom proximalward under the inguinal ligament, the fibrous lamina is found to become the femoral sheath (Fig. 1 c and d). At the inguinal ligament it is continuous with the plate of non fatty tissue which houses the iliac vessels and with the fascial coverings of the abdominal aponeuroses.

In this way the femoral vessels are protected as they lie within the fossa below the level of the falciform margin the saphenous and its tributaries are nearer the skin, yet course along the fascia lata where they are lodged in the fibrous layer of superficial fascia and covered by the fatty stratum.

b *Superficial veins* Before presenting original observations on the saphenous tributaries, it will be helpful to review briefly the standard descriptions of these channels.

The superficial circumflex iliac vein is regularly described as a small but quite constant, vessel which drains the area superior to the lateral half of the inguinal ligament and as far lateralward as the anterior superior spine of the ilium. It is said to be only occasionally duplicated. The vein courses inferomedially

crossing the inguinal ligament obliquely en route to the fossa ovalis, where it may terminate in the great saphenous the femoral the superficial epigastric, or the lateral accessory saphenous vein.

The superficial epigastric vein is likewise small. Arising in the umbilical region some times through anastomosis with the thoraco-epigastric vein the vessel courses inferolaterally over the medial half of the inguinal ligament to the fossa ovalis. Here it empties into the saphenous vein into any one of the latter's tributaries, or into the femoral directly. It may anastomose across the linea alba, with the companion vessel of the opposite side or may communicate with the dorsal penile vein.

The external pudendal is a continuation of the anterior scrotal or labial veins. It commonly receives communications from dorsal penile or clitoral vein and from vessels of the hypogastric region. At the fossa ovalis the pudendal may empty into the great saphenous vein or the femoral or any near tributary (superficial epigastric or accessory saphenous).

Exceeding the above mentioned vessels in size, is a vein which is sometimes termed lateral accessory saphenous. This vessel quite constant in occurrence originates in a suprapatellar network gathering branches from the anterior and lateral surfaces of the thigh. It inclines medially in ascending to the fossa ovalis, where it is likely to empty into the superficial circumflex iliac vein or into the great saphenous vein.¹

The medial accessory saphenous vein is by far the least constant of the proximal femoral group. It drains the posteromedial surface of the thigh and is directed anterosuperiorly to terminate in the great saphenous vein. When such an accessory vessel ascends into the proximal one-fifth of the thigh it usually receives the external pudendal vein near its terminus.²

¹This vessel has been previously described by numerous investigators under the names of external superficial femoral vein (Pernst), lateral superficial femoral vein and lateral femoral circumflex vein (Cunningham), accessory saphenous vein (Tandler), and anterior saphenous vein (Parker and Cherry).

²In the BNA terminology this vein is merely termed the accessory saphenous vein, however the additional designation, medial, must be given to distinguish it from the accessory vessel of the opposite aspect of the thigh. Other terms designating this vessel are lateral femoral cutaneous vein (Tandler), medial superficial femoral vein, medial circumflex femoral vein (Cunningham), posterior saphenous vein (Parker and Cherry).

Fig. 1. Investments of saphenous and femoral veins, successive stages of dissection from superficial fascia (a and b) to fascia lata and femoral sheath (c and d). In Figure 1a, fatty layer of superficial fascia has been removed at fossa ovalis to expose membranous layer where it ensheathes saphenous vein. Figure 1b, fatty layer reflected from area lateral to fossa to show falciform margin and superior cornu. adipose layer is perforated by saphenous tributaries to form fascia cribrosa, and is continuous with similar tissue in depths of fossa. Figure 1c, fatty layer entirely removed to demonstrate manner in which immediately subjacent deep layer of fascia forms a complete sheath (here opened) for femoral vessels. Figure 1d sheath further exposed by cutting it beneath incised distal edge of falciform margin.

While such descriptions account for common anatomical features they leave unrecorded some important details of morphology and incidence of common departures from the anatomic normal. These data will now be presented from the authors' observations.

The patterns formed by the five major tributaries of the proximal part of the great saphenous vein are numerous. There is, however, a marked tendency for two or more of these vessels to fuse into a common venous trunk before entering the great saphenous vein.

of the bilaminar superficial fascia is a fatty stratum while the inner deep layer is fibrous the latter contributes to the formation of a strong membranous investment for the larger vessels of the thigh. It is rather readily separable from the outer adipose layer (Fig 1 a and b). In addition to the superficial veins the subinguinal and inguinal lymph glands are situated in this deep membranous stratum which, in the femoral triangle some times contains an appreciable deposit of fat. When followed into the fossa ovalis, and therefrom proximalward under the inguinal ligament, the fibrous lamina is found to become the femoral sheath (Fig 1 c and d). At the inguinal ligament it is continuous with the plate of non fatty tissue which houses the iliac vessels and with the fascial coverings of the abdominal aponeuroses.

In this way the femoral vessels are protected as they lie within the fossa below the level of the falciform margin the saphenous and its tributaries are nearer the skin yet course along the fascia lata where they are lodged in the fibrous layer of superficial fascia and covered by the fatty atrium.

b *Superficial veins* Before presenting original observations on the saphenous tributaries it will be helpful to review briefly the standard descriptions of these channels.

The superficial circumflex iliac vein is regularly described as a small but quite constant vessel which drains the area superior to the lateral half of the inguinal ligament and as far lateralward as the anterior superior spine of the ilium. It is said to be only occasionally duplicated. The vein courses inferomedially

crossing the inguinal ligament obliquely en route to the fossa ovalis, where it may terminate in the great saphenous, the femoral, the superficial epigastric, or the lateral accessory saphenous vein.

The superficial epigastric vein is likewise small. Arising in the umbilical region, some times through anastomosis with the thoraco-epigastric vein the vessel courses inferolaterally over the medial half of the inguinal ligament to the fossa ovalis. Here it empties into the saphenous vein into any one of the latter's tributaries, or into the femoral directly. It may anastomose across the linea alba with the companion vessel of the opposite side or may communicate with the dorsal penile vein.

The external pudendal is a continuation of the anterior scrotal or labial veins it commonly receives communications from dorsal penile or clitoral vein and from vessels of the hypogastric region. At the fossa ovalis the pudendal may empty into the great saphenous vein or the femoral, or any near tributary (superficial epigastric or accessory saphenous).

Exceeding the above mentioned vessels in size is a vein which is sometimes termed lateral accessory saphenous. This vessel quite constant in occurrence originates in a suprapatellar network gathering branches from the anterior and lateral surfaces of the thigh. It inclines medially in ascending to the fossa ovalis, where it is likely to empty into the superficial circumflex iliac vein or into the great saphenous vein.¹

The medial accessory saphenous vein is by far the least constant of the proximal femoral group. It drains the posteromedial surface of the thigh and is directed anterosuperiorly to terminate in the great saphenous vein. When such an accessory vessel ascends into the proximal one fifth of the thigh, it usually receives the external pudendal vein near its terminus.²

¹This vessel has been previously described by numerous investigators under the names of external suprapatellar femoral vein (Parroty), lateral superficial femoral vein and lateral femoral circumflex vein (Cunningham), accessory saphenous vein (Fauder), and anterior saphenous vein (Fauder and Cherry).

²In the BNA terminology this vein is merely termed the accessory saphenous vein, however the additional designation, medial, seems to be quite in-discriminate if from the accessory vessel of the opposite aspect of the thigh. Other terms designating this vessel are internal femoral circumflex vein (Tobin), medial superficial femoral vein, medial circumflex femoral vein (Cunningham), posterior saphenous vein (Parroty and Cherry).

saphenous veins, are confluent (Fig 2c), the incidence of this arrangement is 13.1 per cent (46 cases, 25 right, 21 left, 2 bilateral)

In type IV the two regular medial veins namely, superficial epigastric and superficial external pudendal veins, fuse before entering the great saphenous vein (Fig 2d), incidence 6 per cent (21 cases 10 right, 11 left, 2 bilateral). This vascular pattern occurs frequently in association with fusion of the two lateral branches (superficial circumflex iliac and lateral accessory saphenous veins) the combination is catalogued as type VIII.

Type V includes cases in which an accessory medial saphenous empties in common with the external pudendal vein into the great saphenous vein (Fig 2c) incidence 7.7 per cent, (27 cases 13 right, 14 left 3 bilateral). In a few instances the medial accessory vessel is present with one or the other of the remaining types, but so rarely that elevation to the status of a separate type is not warranted. A lateral accessory saphenous vein only rarely accompanies a medial accessory saphenous (2 in the 27 cases). This would suggest that when a medial accessory vessel is present, the lower femoral tributaries of the great saphenous vein drain the region usually cared for by the lateral accessory vessel.¹

Specimens designated as type VI are characterized by a fusion of the three lateral tributaries, namely the epigastric, circumflex iliac, and lateral accessory saphenous the single vein thus formed drains into the great saphenous. This pattern is, by far the commonest encountered in the current study (Fig 2f) incidence 33.4 per cent (117 cases, 60 right, 57 left, 19 bilateral).

In specimens of type VII an unusual plan of fusion occurs the superficial epigastric and the lateral accessory saphenous veins join over the fossa ovalis to terminate by a common stem in the great saphenous vein while the circumflex iliac vein and pudendal veins end independently in the main venous trunk (Fig 2g) incidence, 2.0 per cent (7 specimens 4 right, 3 left, none bilateral).

In type VIII dual fusion takes place the circumflex iliac and lateral accessory saphenous

veins on the one side and the external pudendal and epigastric veins on the other form lateral and medial common tributaries respectively (Fig 2h) incidence 7.7 per cent, (27 cases 9 right, 18 left, 5 bilateral).

Viewing the specimens as a group, some additional facts are evident. The tributary most frequently duplicated is the external pudendal vein (54 instances in 350 thighs) however, triplication is rare (2 cases). The next most frequent duplication is that of the superficial circumflex iliac vein which occurs in 4.8 per cent of thighs (17 cases) in over half of these the supernumerary vessel empties into the femoral vein directly. The circumflex iliac is tripled in but one instance. Termination as a single vessel in the femoral vein occurs in 1.7 per cent of specimens (6 cases). The superficial epigastric vein is frequently doubled the arrangement occurs in only 3.1 per cent (11 cases) it is never tripled and is absent in only 1.4 per cent (5 cases). The lateral accessory saphenous vein is duplicated in approximately the same number of cases (10) never present in triplicate.²

The actual specimens, upon which the diagrammatic figures (Fig 2a to 2h) are based present some details of form which require special consideration. Small veins from nearby lymphatic glands are common (at asterisks Fig 3). Not infrequently tributaries enter the saphenous through a bay like 'trunk' as an intermediary (Fig 3a) so that the confluence may be regarded as formed by two tributaries (type II) or by three (type VI). In the present study vessels were considered to empty separately if their common trunk measured less than 2 millimeters in length. Transformation readily occurs when the 'bay' is widened (type I into type VI Fig 2i). Surgically the distinction is unim-

¹The division made by Fowler and Cherry of the superficial epigastric vein into 'satellite' veins (which anastomose directly with the small artery of the same name) and 'accessory' veins (the associated with the external pudendal vein) was investigated. Employing as criterion simply the simultaneous occurrence of both vessels on one side, the arrangement is found to be quite common (4.8 per cent; 17 in 350 thighs).

²The lateral accessory saphenous vein, which occurs commonly in the present authors' series, is not listed in the IMA terminology however as the literature it has been described under a variety of names. Edwards (1930) has pointed out the importance of this lateral vessel from clinical standpoint.

The lateral superficial connections of the dorsal superficial vein of the penis do not alter the present scheme of typing. When such connection exists, it is by way of either a single or double external pudendal vein or by way of a specially duplicated superficial epigastric vein. It has its origin in connection with the left side as was brought out by Ors (quoted by Fowler and Cherry).

³Usually the great saphenous vein divides lower in the leg or receives small branches lower in the leg from the region drained by the medial accessory saphenous vein.

Fig. 4. Types of fossa ovalis, with related vessels. Figure 4a, smallest fossa, Figure 4b, small circular fossa, with femoral artery fully exposed. Figures 4c and 4d, large oval fossa, with femoral artery concealed and femoral vein wholly or partially exposed, saphenous vein receiving deep tributaries within fossa. Figure 4e, large oval fossa, with lateral half of artery concealed by fold-form margin. Figure 4f, largest fossa (in 300) with artery fully exposed. Adapted from Anson and McVay 1938.

cerv (Fig 3d) These may be received proximally rather than distally with the result that several veins from a region converge upon a short trunk (Fig 3d) When a vein drains one area chiefly, but closely skirts another it may receive a tributary from the latter for example an extra epigastric may enter the circumflex iliac (Fig 3c) Almost always the accessory saphenous veins are much smaller than the great saphenous. With similar degree of constancy tributaries empty into the saphenous (separately or by conjoined trunk) on their own side of the chief vessel. Rarely however the superficial epigastric crosses to the lateral side to end on the opposite aspect of the saphenous (Fig 3g) It is important, surgically to know over how great a length of the saphenous vein tributaries of the proximal group will enter the main channel. In a consecutive series the

distance from the termination of the femoral to the most distally placed tributary was 1 centimeter or less in 15 per cent of cases, 1.1 to 1.5 centimeters in 26 per cent, 1.6 to 2 in 24.5 per cent, 2.1 to 2.5 in 16 per cent, 2.6 to 3 centimeters in 9 per cent, 3.1 to 3.5 centimeters in 5.5 per cent, 3.6 to 4 centimeters in 3 per cent and over 4 centimeters in only 1 per cent. This means that in the great majority of cases (96 per cent) the tributaries are received by the saphenous vein in the last 3.5 centimeters of its length, close to or directly over the fossa ovalis.

c. *Fossa ovalis and femoral vessels* The fossa ovalis is regularly pictured as an elongated fault in the fascia lata situated just distal to the inguinal ligament, and as being considerably larger than required for transmission of the saphenous vein. In some illustrations in standard textbooks, the fold

form margin is shown extending lateralward to cover the femoral artery. In others, approximately half the artery's width is exposed beyond the free margin of the fossa. Actually both arrangements are common.

In an earlier study conducted in the authors' laboratory (Anson and McVay 1938) on 200 thighs, the smallest fossa encountered measured 1.6 centimeters in length and was circular in form (Fig. 4a) the largest was 8.5 centimeters long and 3.5 centimeters wide (Fig. 4f). In 90 per cent of the specimens the length was between 3 centimeters (Fig. 4b) and 6.4 centimeters (Fig. 4e) the average length was 4.6 centimeters. In 87 per cent the width was between 3.9 centimeters and 1.5 centimeters the average width was 2.8 centimeters. The femoral vein was found to be exposed through its full width in virtually every specimen. In 83 per cent of 100 consecutive specimens the femoral artery also was wholly or partially exposed. More specifically in 36 per cent three-fourths to all of its width was in view (Fig. 4f) in 30 per cent, one-half to one-fourth (Fig. 4e) not infrequently (17 per cent) the artery was fully exposed with space remaining between the vessel and the margin of the fossa (Fig. 4b). In some cases venous tributaries were found to come forward through the fascial floor of the fossa to empty into one of the lesser tributaries or into the saphenous itself (Figs. 4c and 4d).

2. SURGERY

It is established beyond threat of denial that a surgical technique is best when it pays greatest heed to the normal fabrication of the human body. By the same token it is true that refinement of anatomic concepts of structure makes for less disturbing surgery. When a particular method depends heavily upon anatomical descriptions and figures of stereotyped order—such as are found in standard textbooks—the possibility of technical improvement is decreased, and the surgeon's feeling of security is, as a consequence lowered. But when on the contrary the surgeon is armed with detailed foreknowledge of common variation in structural pattern and has access to actual pictorial records of paramount features in their most

frequent interrelationships, he is equipped to move with ingenuity and surety.

In treatment of varicosities of the saphenous vein and its tributaries, by high ligation, the skin incision begins at the level of the inguinal ligament 2.5 centimeters medial to the femoral artery the pulsations of which are palpable from the surface. An incision 5 centimeters long is found to give satisfactory exposure of the saphenous vein in its proximal portion where tributaries reach the areas of 'torcular' junction of the saphenous and femoral veins.¹ The incision should incline slightly medialward as it descends, to match the long axis of the saphenous vein which departs from the less oblique one of the femoral vein. As mentioned earlier the saphenous vein lies in the deeper layer of the superficial fascia. The chief tributaries are lodged in this layer as are also the lymph glands and their arteries of femoral source and their veins of femoral or saphenous termination. This means that the incision may be carried quite safely through the superficial fatty layer of the superficial fascia.

The saphenous vein is next freed from its fibrous covering of fascia from the point of entrance into femoral downward for a distance of 3 centimeters or more. It is readily distinguished from the femoral vein since the latter lies not only subjacent to the saphenous, but under the superior and inferior margins of the fossa ovalis in which situation it is invested by a fairly heavy prolongation of the femoral sheath. The stripped length of 3 centimeters is almost always sufficient to expose all of the converging tributaries in the present authors' studies it was found that the area of reception of tributary veins rarely exceeded that length.

Since any or all of these tributaries may open into the broadened saphenous at its junction with the femoral the confluence is then to all intents and purpose with the femoral itself. From the surgical standpoint this means that it is unsafe to ligate the saphenous only the tributaries should be

¹In this and in preceding parts of the discussion the account of technique has been adapted from Oschner and Mahomet's excellent monograph; the observations on anatomy are the joint conclusions of the several co-authors of the present article, while the surgical notes are based upon observations made by the senior author, Dr. E. H. Incester.

ligated separately (Fig 5) At first sight it might be considered satisfactory to ligate the confluent channel (cf Fig 2f) Actually how ever such a procedure would be venturesome since the channel being short might not retain a ligature after excision of a segment of the great saphenous vein (see hereinafter) All of the tributaries of the saphenous should be ligated, since unligated veins even when small, are likely to bring on recurrence of the varicosities especially in the case of the lateral accessory branch. It is worth recording that several cases have been observed in which large lateral accessory branches have been mistaken for the great saphenous vein and ligated in its stead and that lateral accessory saphenous branches which are equal to or larger than the great saphenous trunk are not uncommon

In mobilizing the saphenous vein and its satellites it is advisable to free the vessel somewhat from its ensheathing tissue proximalward to its point of junction with the femoral in order to be certain of the position of the latter Failure to make adequate exposure in a case recently observed, led to misidentification of the femoral vein mistaken for the great saphenous the femoral was ligated and severed.

It is important to realize that varicose dilatation of a tributary may simulate hernial enlargement, when the swelling lies over or near the fossa ovalis. One of the authors has seen a case in which enlargement of the superficial circumflex iliac vein was incorrectly diagnosed as a femoral hernia.

Regardless of whether the tributaries be closely grouped in tunicular fashion or segregated, a segment of the saphenous trunk should be removed (between proximal and distal ligatures) to render improbable regeneration and re-establishment of vascular connections (Fig 5) Simple ligation without severance of the saphenous vein or of its tributaries is likely to result in recurrence of varicosities The proximal ligature should be placed as near the point of emptying of saphenous into femoral as is technically possible. When a long proximal stump of the saphenous remains the possibility of thrombosis, with subsequent embolism, is greatly increased

Fig 5. Technique of high ligation of saphenous vein and tributaries: two patterns of venous pattern shown. Stippled area indicated segment to be removed after ligation.

Removal of a segment of the saphenous is the only dependable way of providing a substitution valve in the territory of the saphenofemoral junction. Because varicosities in the saphenous system are the result chiefly of valvular incompetence at the saphenofemoral junction ligation of proximal tributaries only would bring relatively slight hydrostatic relief to the main recipient vein (i.e. saphenous). But when the saphenous (with its weakened valves) is ligated and cut, recurrence is obviated the most troublesome segment has been extirpated and the vascular stream has been strongly diverted through numerous lesser channels whose structure is less impaired.

Several additional anatomical features require practical consideration. These are the regular presence of branches of the femoral artery in and near the fossa ovalis the exposure of the femoral artery itself within widely open fossae the occurrence of communicating veins from deep (muscular) level and of veins received from lymphatic glands.

The arteries referred to are those for which the veins herein considered serve as *venae comites*. Usually they match each other in course. Sometimes, however the arteries pass beneath the saphenous en route to their areas of inguinal, femoral or pudendal supply or emerge through lesser hiatuses in the fascial margin of the fossa ovalis being thus unpredictable in position. This feature coupled with the fact that they are occasionally large makes it advisable to exercise care

in mobilizing the tributary veins where they reach the fossa. Transection of the arteries could cause troublesome bleeding.

While the femoral artery is more likely to be beneath the deep fascia at the falciform margin than to be exposed medial to the latter's free edge, instances are not uncommon in which the latter arrangement obtains (Fig 4). In rare instances the artery is exposed in full width and for a length of 8 centimeters or more. Although fossae tend to be wide when they are long and hence assume an oval outline, exceptional width may be exhibited by fossae of ordinary length—so that the femoral artery lies unguarded in a circular fossa.

It is well known that communications with veins of muscular level occur at variable intervals along the entire course of the greater and lesser saphenous veins; they pass through small hiatuses in the pedal crural and femoral portions of the deep fascial investment of the lower extremity. It is not generally recognized however that vessels of communicating type may occur within the confines of the fossa ovalis. Such vessels emerge through the pectineal fascia on the floor of the fossa, to terminate quickly in the saphenous vein (Fig 4c and 4d) or in the femoral. In "anchoring" the saphenous to subjacent veins they render mobilization of the vessels more difficult.

Veins draining the lymph glands of the inguinal and subinguinal groups are regularly of dissectable size and occasionally as large as the epigastric and circumflex iliac veins (Fig 4a). They could cause troublesome bleeding were they inadvertently cut and left unligated. The same would apply to transection of the companion arterial branches from the femoral.

CONCLUSIONS

In a study of the subcutaneous veins tributary to the great saphenous vein at or near the latter's termination in the fossa ovalis, it was found that vascular patterns (from 350 thighs) could be arranged in eight general types according to the degree of complexity and of tributary fusion. Fusion of two adjacent tributaries entering one side of the saphenous vein occurs very frequently fusion to produce a common trunk on each of the two

sides in the same specimen is uncommon as is also independent termination of all tributaries. However no matter whether conjunction or separateness obtains, the tributaries enter the saphenous vein over the area of or just distal to the lower margin of the fossa ovalis in more than half of the cases they enter the saphenous in its upper 2 centimeters, and rarely over an area greater than 3.5 centimeters in length (measured downward from the femoral termination of the saphenous). These observations mean, surgically that the area of required exposure of the saphenous vein need not be extensive a length of approximately 4 centimeters would be more than adequate in most instances. Width of the area would be governed by the type of tributary pattern revealed in tracing the veins peripheralward from their terminations.

These venous channels from abdomen, perineum and thigh are lodged in heavy fibrous tissue which lies just external to the deep fascial investment (*fascia lata*) of the musculature of the thigh; only their lower tributaries course through the fatty pannicle from subcutaneous level. As the larger veins (epigastric, pudendal, etc.) approach the saphenous, the fibrous tissue forms for them a grossly demonstrable coat, which, traced with them into the fossa ovalis, becomes the strong femoral sheath. This sheath is actually bilaminar its outer lamella being a prolongation under the inguinal ligament, of the transversalis and iliac fasciae, its inner lamella being a similar derivative of the heavy fibrous layer of retroperitoneal tissue. The main venous tributaries of the saphenous thus lie next to the *fascia lata*, their depth below cutaneous level increasing with obesity of the subject. The femoral vein is situated on the floor of the fossa, upon the fascia covering the pectineus muscle. Its free (anterior) surface is flush with the plane of iliac (lateral) portion of the *fascia lata* where the latter forms the falciform margin of the fossa. This is tantamount to saying that, from the surgical standpoint, the veins which come into the field of varicosity ligation are predictably located in relation to fascial planes, and, to some extent, protected from inadvertent transection. The femoral artery in more than

three fourths of cases is exposed within the fossa (i.e. extends medially beyond the falci form margin) for part or all of its width—a circumstance which requires care in dissecting down upon the adjacent femoral vein.

The regular occurrence of iliac epigastric, and pudendal branches of the femoral artery and the occasional presence of intrafossal venous tributaries from muscular sources are additional anatomical features which increase the need for surgical caution.

THORACOABDOMINAL WOUNDS

A Review of 270 Cases

DENNIS B. FOX, M.D., Captain, M.C., A.U.S., Randleman, North Carolina

THIS report is a review of patients with thoracoabdominal wounds admitted to a General Hospital in Italy between November 16 1943 and February 28 1945. The data were obtained from a survey of the total admissions of American or Allied troops. During this period 270 patients were admitted with the diagnosis of one or more perforations of the diaphragm. This number represents an incidence of 1 per cent of the total of 26,852 patients admitted, and 1.9 per cent of the total of 14,112 patients who were either battle casualties or injuries. The report does not include a rather large number of patients who had separate penetrating wounds of the abdomen or chest. It reviews only those patients who had a perforation of the diaphragm by a metallic foreign body.

Between April 1 1944, and December 30 1944 this hospital functioned as an active chest center. During this period there were exactly 1,000 patients admitted to the chest service. One hundred and eighty-two (18.2 per cent) of these patients so called chest cases, had thoracoabdominal injuries.

All patients in this series were white males except one a negro. Their average age was in the low twenties.

Fifty-two cases (19.3 per cent) were due to machine gun or gunshot wounds, and 218 (80.7 per cent) were due to shell fragments.

The report will be discussed under the following division: (1) type and incidence of traumatic lesions, (2) therapy in forward hospitals, (3) therapy in the general hospital, (4) complications, (5) results and disposition of patients, and (6) summary.

TYPE AND INCIDENCE OF TRAUMATIC LESIONS

Few thoracic and abdominal organs are immune to injury in penetrating or perforating

thoracoabdominal wounds. In this series, the adrenals and bladder are the only organs which were not injured. Table I shows the variety and incidence of the various thoracoabdominal lesions and the more serious of the concomitant lesions sustained by the patients. Only 48.5 per cent of the patients had pneumothorax, hemothorax, or hemopneumothorax. It is believed that the actual incidence was higher but the degree was so mild that the condition was not listed as a diagnosis.

THERAPY IN FORWARD HOSPITALS

The possibility that a bullet or shell fragment may have perforated either the thoracic cavity or abdominal cavity or both is the problem that presents itself with each patient who sustains an injury to the chest or abdomen particularly the lower chest. It requires skillful surgical judgment in the early evaluation of the lesions in these patients and no less skill in the proper operative treatment. In penetrating as well as perforating tangential wounds the surgeon must choose between an exploratory laparotomy, thoracotomy, thoracotomy with transdiaphragmatic abdominal exploration, a separate thoracotomy and laparotomy, or a simple débridement of the wound. That no one approach has found universal favor is shown by reference to Table II. One patient had a left thoracotomy, a laparotomy and a right thoracotomy at his initial operation.

X-ray films in suspected thoracoabdominal injuries may be misleading particularly if the plate is underexposed, if read when wet and by an inadequate light. Under these conditions small intra-abdominal foreign bodies may be overlooked. Early clinical signs may also be mild or be masked by other injuries such as brain or spinal cord lesions, burns, severe fractures and similar injuries. It is to the credit of the surgeons in the forward hospitals, therefore, that only 5 of the 270 pa-

Laceration right common iliac vein	1	0.4

tients with thoracoabdominal injuries were evacuated to the base hospital without the presence of thoracoabdominal injury having been recognized and without any operation having been done. These patients were evacuated during periods of extreme activity on the front at which time large numbers of casualties were flooding the field and evacuation hospitals. Two of these patients were received within 24 hours after injury so the time interval was not greatly in excess of that which would have elapsed had the patients had an operation in the forward hospitals. Two were received and operated upon 3 days after injury. Another had no immediate serious consequence of the wound and had no operation.

The variety of primary surgical procedures which were necessary is shown in Table III. The records showed only 60.5 per cent of the cases in which the diaphragm had been su-

TABLE II.—PRIMARY OPERATIONS AT FORWARD HOSPITALS

Operations	Cases	Per cent
Thoracotomy	70	25.3

Total	248	100.0
(No record available as to type of operation)	21	
Total	270	

tured. In only 1 case however was mention made that the diaphragm was *not* sutured. Similarly only 9.7 per cent of the cases were reported to have closed intercostal catheter drainage of the pleural cavity following initial operation. Only one half of the total number of patients having a wound of the liver had postoperative subcostal drainage of the liver or the subphrenic space.

Practically all of the patients received transfusions and plasma before and after the initial operation as well as sulfonamide penicillin or both. Records were not available as to the duration of therapy with these drugs. Sulfadiazine was the sulfonamide usually given and was administered in doses of 1 gram every 4 hours. Penicillin was given in the dosage of 25,000 units every 3 hours.

THERAPY IN THE GENERAL HOSPITAL

For the entire group of cases the average time after injury until admission to this hospital was 18.9 days. The longest time interval was 129 days, the shortest 1 day.

It is interesting and very important to note that 43 per cent of the patients required no further operation at the base hospital. This does not mean that the patients did not require further therapy. On the contrary many of the patients required a great deal of attention such as frequent thoracentesis, blood and plasma transfusions, dressing of wounds and colostomies and changing of casts. The most frequent surgical procedure was wound closure. A total of 98 patients, 36.3 per cent, had secondary closure or secondary closures plus skin grafts. Thoracotomy for empyema was performed in 30 cases, 11.1 per cent. This pro-

cedure usually consisted of a resection of a few inches of rib under local anesthesia and institution of closed drainage. A decortication of the lung was done in 3 cases for chronic empyema and also in 2 cases for organizing clotted hemothorax. An attempt was made to perform decortication of the lung in another case with chronic empyema but without success. There was an exploration of the subphrenic space in 14 patients 5.2 per cent and 11 of these had a subphrenic abscess which was drained. Table V shows the other procedures performed at this hospital.

Of the 5 patients admitted without previous operation 4 had primary débridement and operation as follows (1) thoracoabdominal exploration splenectomy suture of the diaphragm débridement of wounds (2) abdominal exploration, splenectomy suture of diaphragm débridement of wounds (3) abdominal exploration, suture of jejunum su-

COMPLICATIONS

Seven patients in this series died which is a mortality rate of 2.6 per cent. A brief summary of these cases follows:

CASE 1: A white male, aged 28 years, was admitted 38 days after injury, in which he sustained a penetrating wound of the left thorax, with laceration of pleura, diaphragm, stomach, and spleen. He developed empyema of the left pleural space and an

embolic hemolytic staphylococcus brain abscess and died 9 days after admission, 47 days after injury.

CASE 2. A colored male, aged 25 years was shot one day before admission to this hospital. He had a sucking wound of the right lower chest which was debrided and closed at a nearby station hospital. He was transferred to this hospital because of evidence of continued intrathoracic hemorrhage. On the day of admission to this hospital a thoracotomy was performed through the right eighth intercostal space, the liver was packed and drained subcostally, the diaphragm was closed, a bleeder in the pericardial fat was ligated, a laceration of the lung was sutured, intercostal underwater catheter drainage of the chest was established and following bronchoscopy, the patient returned to the ward in good condition. He had a sudden cessation of respiration approximately 30 minutes after returning to the ward and expired. No cause was found for his death.

CASE 3. A white male, aged 23 years, was admitted 10 days after his original injuries which consisted of a penetrating wound of the right thorax with a laceration of the lung, diaphragm, and liver. He also had a wound of the right hand with a fracture of the second metacarpal. At a forward hospital the primary treatment consisted of a thoracotomy with removal of the foreign body from the liver. A muscle transplant was placed in the liver laceration and the diaphragm was sutured. The pleural cavity was drained by catheter postoperatively. The patient ran high fever after admission to this hospital and expectorated bile-stained sputum and vomited bile several times. He was thought to have a subhepatic abscess and operation for drainage was to be performed, but he died shortly after the anesthetic was started. Death occurred 19 days after injury. At autopsy he was found to have subphrenic and subhepatic abscesses as well as an abscess of the liver and a peritoneophrenicobronchial fistula. He also had a massive retroperitoneal hematoma, the cause of which was undetermined, a bronchopneumonia of the right lower lobe of the lung and dilatation of the right side of the heart.

CASE 4. A lieutenant, 24 years of age, was admitted 21 days after injury. He sustained multiple penetrating wounds of the right sternal region with penetration of the right lobe of the liver, wounds of the left scalp, left arm, right thigh, and left shoulder. At forward hospitals he had had a debridement of his wounds, an exploratory laparotomy and several days later drainage of a subphrenic abscess. At this hospital he had a secondary closure of his wounds and an exploratory laparotomy 45 days after injury with drainage of the subphrenic space. He developed multiple biliary fistulas of the abdominal wall and after a long, very stormy course finally expired 45 days after admission, 66 days after injury.

The principal autopsy findings were multiple liver abscesses, subphrenic and subhepatic abscesses, bacteremia due to *Aerobacter aerogenes*, peritonitis, acute bile nephrosis, cholangitis, acute empyema, right bronchopneumonia, left dilatation

of the heart, severe atelectasis of the right lower lobe of the lung, hyperplasia of the bone forming elements of the bone marrow.

CASE 5. A white male, aged 27 years, was admitted to this hospital 29 days after injury. He sustained a penetrating wound of the lower right chest with penetration of the right pleural cavity, diaphragm, and a laceration of the right lobe of the liver. The day following injury at a forward field hospital he had an exploratory laparotomy. A large wound of the liver was found and packed for a period of 10 days, after which the packing was removed. Shortly after the operation, the patient developed ascites and pitting edema of the ankles. He complained of an uncomfortable full feeling in his abdomen and anorexia. Examination on admission to this hospital revealed signs of free fluid in the abdomen with edema of the ankles and toes. There was no evidence of collateral circulation. The liver was not palpable. X-ray examination of the chest showed some elevation of the left diaphragm. The patient ran a temperature in the vicinity of 99.4 degrees during his stay in the hospital. Six days after admission he was given a cubic centimeter of salyrgan and had a marked reduction in the size of the abdomen and moderate diminution of the edema of the feet. Seventeen days after admission the patient walked to the latrine, and while having an apparently normal bowel movement, suddenly developed weakness, air hunger and cyanosis, and expired approximately 10 minutes later. Essential autopsy findings were a massive subphrenic abscess, chronic, right, with terminal rupture into the peritoneal cavity, peritonitis, acute, diffuse, severe terminal atelectasis of lung bilateral, due to compression, cardiac dilatation marked, right.

CASE 6. A white male, aged 23 years, was admitted to this hospital 17 days after injury. He had received a penetrating wound of the left thorax just below the nipple. The shell fragment passed through the pleural space, lacerated the apex of the pericardium, perforated the diaphragm and lodged in the right lobe of the liver. Primary operation consisted of a laparotomy with suture of the diaphragm. The liver laceration was noted but there was no active bleeding. The foreign body was not removed. The chest wound was debrided and one suture was taken in the pericardium and the wound was closed. Four days after injury he began having chills and fever and was diagnosed as having malaria, though smears were negative. He was not acutely ill, and his condition was fairly good on admission. Shortly after admission, he began having almost daily chills and fever of 103 to 104.5 degrees F. Repeated malarial smears were negative. The patient became jaundiced and it was felt that he probably had a subphrenic abscess or a liver abscess or both. Two blood cultures were positive for *Escherichia coli* and two were negative. He did not improve with penicillin given in doses of 25,000 units every 3 hours or to heavy doses of sulfadiazine. Forty days after injury a first stage operation for exploration of the

Thrombophlebitis	3	1.1

right subphrenic space was done and the second stage 10 days later but no pus was found in the subphrenic space nor was any pus obtained with aspiration of the right lobe of the liver. In spite of tremendous quantities of blood and plasma, the patient's blood cells, hemoglobin and serum protein remained low and he developed peripheral edema. This improved with the administration of human serum albumin daily in 100 cubic centimeter doses for 5 days, but the constant septicemia gradually debilitated the patient and he finally expired 50 days after admission, 67 days after injury. Autopsy revealed a small metallic foreign body in the right lobe of the liver which was lying partly within the lumen of a fairly large branch of the hepatic v. i. There was a very small abscess cavity about the foreign body

and some abscess formation had occurred along the missile tract and had apparently recently ruptured into the abdominal cavity. Microscopically the liver showed numerous minute abscesses.

CASE 7 A white male, aged 30 years, was admitted 9 days after having sustained a gunshot wound of the right shoulder which passed through the right thoracic cavity lacerating the diaphragm and liver. He also had a wound of the right hip with an incomplete fracture of the greater trochanter of the femur. Original treatment consisted of débridement and suture of the thoracic wound, a laparotomy and suture of the diaphragm with subcostal drainage of the subphrenic space. Four days after admission he developed a tension pneumothorax on the right and the following day on the left and in spite of bilateral intercostal thoracotomies with catheter drainage the patient expired 5 days after admission, 14 days after injury. Autopsy findings were atelectasis, bilateral, marked hydropneumothorax, right, moderate cardiac dilatation, marked abscess, subdiaphragmatic, right congestion of viscera, marked and extremely wounds as described above.

Table VI shows that the most frequent complication was empyema. There were 43 cases of empyema, an incidence of 15.9 per cent of the 270 cases reviewed. There was only 1 case of empyema which did not have a perforation or laceration of some thoracic or abdominal organ. Of the 43 cases of empyema only 2 4.9 per cent were able to return to limited duty. The others were evacuated to the Zone of Interior for further convalescence. In only one case was there a large persistent empyema cavity present when the patient was evacuated. The average number of days after injury until thoracotomy for empyema was done was 26.6. Only 2 cases of clotted, organizing hemothorax resulted from a total of 131 cases in which a diagnosis of hemothorax or hemopneumothorax was made. In the majority of the cases repeated thoracenteses were done and these were sufficient to cure the hemothorax entirely. It is interesting that clinically only 4 cases 1.4 per cent had atelectasis. This low incidence is probably due to the frequency of bronchoscopy following thoracic and thoracoabdominal operations. There were 17 cases, 6.3 per cent who developed a subphrenic abscess, though the incidence in those cases with previous drainage and without previous drainage at the initial operation was practically the same. However, those patients who had subcostal drainage in liver injuries seemed to do better clinically than

did those who had no drainage. There was a remarkable absence of generalized peritonitis and a low incidence of localized abscess formation in the abdominal cavity. It is believed that early operation and postoperative treatment with penicillin or n sulfonamide or both in these cases are largely responsible for the low incidence of infection and abdominal complications in general. Only 3 cases, 1.1 per cent, had a diagnosis of intestinal obstruction made and 2 of these were from paralytic ileus. Four cases, 1.4 per cent, had abdominal billy fistula and one had a combined billy and urinary fistula of the right flank. The patient with billy fistula and with hepatophrenicopleural fistula were in general the sickest patients and required more and closer attention and care than did any others of the group. Eight patients, 3 per cent, developed hepatitis with jaundice. It was not determined if this were secondary to the liver injury or if the patient developed the infectious hepatitis which was prevalent in the theater at this time. Acute thrombophlebitis developed in 3 patients, 1.1 per cent. One patient had a phlebotomy and ligation of his femoral vein. There was no record of therapy on the other two.

RESULTS AND DISPOSITION OF PATIENTS

Table VII shows that 8.9 per cent of the patients were able to return to full combat duty an average of 60 days after injury.

An example of this class was the case of a 25 year old white male who was admitted to this hospital 8 days after receiving a penetrating wound of the right thorax with laceration of the diaphragm and liver. He had a thoracotomy after partial resection of the

seventh and eighth ribs, and the diaphragm was sutured. He had an exploratory laparotomy but no visceral damage was found except a laceration of the liver, which was packed. The only therapy at this hospital was repeated thoracenteses for the hemothorax on the right. The patient was dismissed to full duty 41 days after admission or 49 days after injury.

There were 82 patients, 30.4 per cent, who were returned to limited duty in this theater.

An example of this class was the 29 year old white male who was admitted to this hospital 11 days after receiving a penetrating shell fragment wound of the left chest. His injury consisted of a sucking chest wound, a compound fracture of the left ninth rib, a laceration of the left diaphragm, left kidney and spleen. Treatment at a forward hospital consisted of a thoracotomy with transdiaphragmatic abdominal exploration, splenectomy, and drainage of the left peritoneal space through a flank wound. The diaphragm was sutured and the thoracotomy wound closed. Postoperatively he had a hemothorax of the left pleural space. The only treatment required at this hospital was thoracenteses to remove the hemothorax. His convalescence was uncomplicated and he was dismissed to limited duty 55 days after admission, 66 days after injury.

Over one half the patients, 55.5 per cent, in this series were evacuated to the Zone of Interior for further convalescence. Many of these patients, however, were evacuated because of concomitant lesions and not directly due to the thoracoabdominal injury or its complication (see Table I).

An example of a patient with a thoracoabdominal complication was the 25 year old white male who sustained a gunshot wound of the right thorax with a laceration of the lung, diaphragm, and liver. Primary treatment consisted in débridement and closure of the sucking chest wound. Thoracenteses were performed postoperatively and 12 days after injury at a forward general hospital he had inter

costal catheter drainage of the right chest because of bile stained pus in the right pleural cavity. Twenty-four days after injury he had a decortication of the right lung and a closure of a bronchial fistula, and the wound in the diaphragm was closed. Thirty-six days after injury he had a thoracotomy for drainage of a recurrent empyema, and this procedure was repeated 44 days after injury. The patient was transferred to this hospital 66 days after injury and several days later incision and drainage of a subphrenic abscess were done. On the 79th day from the onset of his illness, another exploratory thoracotomy was done with the purpose of doing another decortication because of a persistent, large empyema cavity. It was found to be impossible to decorticate the lung, so the patient was evacuated to the Zone of the Interior 125 days after injury with a large residual empyema cavity. This was the only patient in the entire series who will probably have a considerable degree of permanent disability as a result of his thoracoabdominal wound.

Seven patients in this series who died have been discussed above.

Seven of the patients were evacuated to North Africa and their final disposition is not known.

In the majority of the patients evacuated to the Zone of the Interior their wounds and colostomy if present, were closed and healed. It is believed that only an extremely small percentage of these patients would require future surgery as a result of their thoracoabdominal wound and that the permanent disability therefrom should be practically nil.

SUMMARY

The incidence of thoracoabdominal injury was 1 per cent of all admissions to this hospital

and 1.9 per cent of all battle casualties and injuries admitted.

A wide variety of lesions resulted from thoracoabdominal wounds but the principal organs involved were the liver 57.4 per cent the lung 34 per cent the spleen 23 per cent kidneys 13.3 per cent the stomach, 13 per cent.

The patients were operated upon by a number of different surgeons, who used a variety of approaches, and no one operative procedure has found unusual favor over another.

The average time after injury until the patients were received at this hospital was 43 days. After arrival only 43 per cent required further operation which consisted primarily of secondary closure of wounds with or without skin grafting in 36.3 per cent of thoracotomy for empyema in 11.1 per cent exploration of the subphrenic region in 4.4 per cent colostomy closure in 4.4 per cent decortications or 1.8 per cent 3 for em and 2 for organizing hemothorax.

The mortality rate was 2.6 per cent series of cases. Complications were relatively few with empyema occurring in 15.9 per cent of cases and subphrenic abscesses developed in 6.3 per cent. In 9 cases transdiaphragmatic abdominopleurobiliary fistulas developed. There were no thoracoabdominal complications in 63.7 per cent of the cases.

There were 24 patients who were able to return to full duty and 82 who returned to limited duty a total of 39.3 per cent of the patients who were of further service to the 1st Theatre of Operations.

DECORTICATION IN ACUTE EMPYEMA THORACIS

PAUL W. SANGER, M.D. Lieutenant Colonel M.C. A.U.S., Charlotte, North Carolina

THE radical management of empyema thoracis in the acute and subacute phases is an attempt to eliminate chronic empyema. That there is a place for pulmonary decortication in certain cases of acute empyema is now well established. It is the purpose of this paper to discuss briefly the problem and then to present case reports which may be of value in establishing the proper indications for radical or conservative therapy.

Decortication was first practiced in this theater in cases of massive clotted hemothorax.¹ Four weeks after wounding now is considered to be the optimum time for its performance in uninfected cases. Later the same operative procedure was adopted in the management of infections in clotted hemothoraces. In these cases the operation is performed as soon as the presence of infection is established. A few have extended the use of this procedure to the management of the more severe infections in both post-traumatic and postpneumonic empyema. Some have attempted to differentiate infected hemothorax and empyema in discussing post-traumatic infections within the pleura. However, the dividing line is not clear. Without proper therapy the infected clotted hemothorax may result in a most disabling chronic empyema. With radical surgical attack the illness in acute severe post-traumatic or post-pneumonic empyema may be shortened to a few weeks. Infected hemothorax properly may be called empyema.

The writer has formed the following opinions: (a) Closed or open drainage (thoracostomy) is the procedure of choice in small and moderate sized, unilocular post-traumatic or postpneumonic empyema. (b) Thoracotomy with evacuation of the pleura and decortication of the lung is the procedure of choice in multilocular empyema and in total empyema with collapse of the upper lobe. In this group

fall both post-traumatic and postpneumonic infections, including those which develop in large clotted hemothoraces.

The technique of pulmonary decortication has been described by Burford and Samson. Essentially the same technique has been used in the cases which form the basis of this report. Certain points should be emphasized: (a) Intratracheal gas-oxygen-ether is the anesthetic of choice. (b) Prior to operation a cannula should be placed in an ankle vein through which blood may be administered as indicated throughout the operation. (c) Posterolateral thoracotomy with or without rib resection is the preferred approach (Fig. 1). (d) All free fluid and clot are removed from the pleural cavity. (e) The fibrinous membrane-like envelop which encases the lung must be completely extirpated. An attempt is made to develop a cleavage plane between the pleura and this organizing exudate (Figs. 2 and 3). In some cases this is easily accomplished; in others it may be most difficult or impossible. In empyema the fibrinous membrane may be much more densely adherent to the pleura than in uncomplicated clotted hemothorax. It is undesirable to traumatize or remove the visceral pleura but occasionally this is inadvertently done. The resulting air leaks may be plugged with fibrin foam but if this is not completely successful, the multiple catheters which are routinely used, maintain expansion of the lung until the small fistulas are occluded. The fibrinous membrane should be removed from all parts of the visceral pleura including that in the fissures so that complete re-expansion is possible (Fig. 4). (f) It is not necessary to remove the exudate which is densely adherent to the parietal or diaphragmatic pleura. (g) It is well to test for air leaks with physiological salt solution after re-expansion of the lung prior to closure. (h) Large mushroom catheters, size 28 to 34, are placed in the 2d interspace midclavicular line, in the 8th interspace at the posterior axillary line, and in the costophrenic sulcus in the anterior axillary line.

¹Gerson, Paul C., Burford, Thomas H., Brewer, Lyman A., III, and Benkert, Benjamin. The management of war wounds of the chest in a basic center. J. Thorac. Surg. (in press).

These are all connected to separate water-sealed bottles which are placed at least 18 inches below the level of the catheter (i) Intercoastal nerve block with 1 per cent novocain is routinely done at the conclusion of the operation (j) Penicillin 100,000 units in 50 cubic centimeters of physiological salt solution is instilled into the pleura just prior to closure. The posterior catheter is left clamped for a period of 4 hours. (k) Penicillin is given intramuscularly 25,000 units every 3 hours for a minimum period of 24 hours prior to operation and is continued postoperatively as long as indicated.

Penicillin has been given credit for the success of this radical surgery in empyema. It has, at least given the surgeon courage to proceed in the presence of severe infection. Its importance however may have been overrated. It is interesting to note that in one case to be described no penicillin therapy was used. In several other cases gram negative bacilli were the offending organisms. The mechanical factors probably are of much more importance than is chemotherapy. Removal of clot fluid, and fibrinous exudate eliminates most of the culture media for the organisms present. Multiple empyema cavities are converted into one. This cavity is largely obliterated immediately by the re-expansion of the incarcerated lung.

In the author's limited experience with decortication in the management of acute empyema, there have been no fatalities. The cases presented below are representative of the more severe types of infection.

CASE 1: An infantryman was admitted to an evacuation hospital 3 hours after sustaining multiple wounds from a rifle bullet with perforating wound of the right chest, bilateral hemopneumothorax, right abdomen, and paralysis of both lower extremities.

The patient was resuscitated and stabilized before a thoracotomy was performed. At thoracotomy there were revealed intercostal bleeding and perforation of the left diaphragm, as well as two holes in the stomach. The openings in the stomach were closed, the diaphragm was approximated with interrupted silk sutures, then the left chest was closed without drainage. The sucking wound of the right chest was simply debrided and closed. A suprapubic cystostomy was done at this time.

He remained in a critical condition for several days. Six days afterward, in a posterior shell with a suprapubic catheter he was evacuated to a general hospital. Admission note recorded. His condition was fair with complete motor loss of both lower extremities,

as well as loss of sense of touch, pain and position." The patient was moderately dyspneic with signs (initial X-ray films are not available) of fluid at his right base, but aspiration withdrew only 150 cubic centimeters of thin, turbid exudate, which by culturing grew gram negative bacilli. X-ray examination disclosed a bullet lying in the spinal canal at the level of the 1st lumbar vertebra. Emergency laminectomy 12 hours after admission, was performed and the cord was found irreparably damaged. The bullet was removed. The admission temperature was 103.8 degrees F. Postlaminectomy temperature for 10 days ranged from 102 to 103 degrees F. Repeated chest taps on the right obtained only small amounts of foul smelling fluid. X-ray pictures then showed fluid and thickness over the pleura virtually obliterating the right lung shadow.

In view of the fact that the urine was negative and the wounds relatively clean, it was obvious that the pyrexia was all due to the empyema. A catheter was placed in the 6th interspace, posteriorly but drained only a small amount of thick, foul pus.

Fifteen days after admission thoracotomy with decortication was done even in the face of a temperature of 104 degrees F. The thoracic cavity was entered through a posterolateral incision in the 5th interspace. Multiloculated pockets of gelatinous, purulent exudate were found. The lung was collapsed and adherent in the posterior gutter area. A thick organized membrane varying from 1 to 4 centimeters in thickness covered the entire visceral and parietal pleura—this served to obliterate the lung in a collapsed position. The adherent capsule-like sheet was extirpated from the visceral pleura with careful blunt and sharp dissection. Bleeding was quite profuse. It was surprising to note that there was a definitely established vascularity between this fibrous layer and the visceral pleura. At several sites the visceral pleura was torn—attempts were made to close the pleural rents but a small amount of air continued to leak after the lung was inflated, for which reason two anterior as well as one posterior catheters were used. At completion of the operation the lung was re-expanded to 90 per cent of its normal extent. The patient was in very poor condition. Blood pressure had fallen perceptibly and only by forcing blood, cambrine, and artificial respiration was he resuscitated.

During the operation this patient received 1500 cubic centimeters of blood, 500 cubic centimeters of plasma, and 500 cubic centimeters of saline. He was in fair condition on return to the ward. Oxygen was continued and the tubes were connected to water seal bottles.

The postoperative course was surprisingly uneventful in view of his critical preoperative condition (complete transection of his spinal cord). The anterior catheters were removed in 7 days as the lung appeared to be sufficiently out and adherent—the posterior catheter was removed 12 days postoperatively. Chest aspiration was necessary on 3 later occasions. Preoperatively and postoperatively this patient was

Fig 1. Technique employed in performing thoracotomy with rib resection. An intercostal approach is optional. Cross section is of chest with total multiloculated empyema and collapse of the lung

given large quantities of penicillin as well as sulfathiazole.

Unfortunately, a postoperative x ray film is not obtainable.¹ At the time of his evacuation to the rear 4 weeks after decortication the x ray report reads "Absence of former density and complete expansion of the upper lobe however the diaphragm remains elevated." Nine weeks after decortication the following letter was obtained from the rear hospital to which the patient had been evacuated. At this time his condition relative to pulmonary status is excellent. There is minimal thickening of the chest in the right anterior base. The right lung appears fully expanded. The soldier is afebrile with no complaints of his chest or breathing. As you might judge there has been no change in his paralysis.

Any patient that is so physically handicapped with a complete transection of the cord so extremely toxic with a temperature of 105 degrees F and without the will to live is the worst imaginable operative risk. Ordinarily

one would defer from proceeding with a hazardous operation but in this incident such an undertaking offered his only chance of survival. The results amply justified this risk.

CASE 2 This American soldier was wounded by a shell fragment which produced a perforating wound of the left chest. He lay in an Italian hospital unattended 4 days prior to admission to an evacuation hospital acutely ill with grossly infected superficial wounds and empyema. Treatment was supportive with repeated chest aspirations. Hemolytic streptococci were cultured from the fluid aspirated.

Three days later the patient was transferred to a general hospital. He was in fair condition: dyspneic, temperature 102 degrees F with signs and symptoms (Fig 5a) of pocketed fluid and thickened pleura in the entire left chest area. He coughed continuously producing copious quantities of white frothy sputum without odor. Four hundred cubic centimeters of brownish foul fluid was aspirated from the 7th interspace in the posterior axillary line at which site a No. 24 French catheter was placed through a trocar—specimens taken produced a growth of hemolytic streptococci and gram negative bacilli on culture. The

¹Some of these patients were operated upon 1. base hospital while I was there on temporary duty. Consequently many x-ray pictures are evacuated with the patients prior to the accumulation of the material for this paper.

Fig. 2 Technique employed in developing cleavage plane between the organizing exudate and the visceral pleura.

temperature remained elevated to 103 degrees F even though the catheter drained satisfactorily. Further aspiration revealed localized cavities in the anterior and midaxillary areas for which reason (multiloculated empyema) it was deemed wise to proceed with thoracotomy and decortication. In the interim the patient was supported by several transfusions during

Fig. 3 Method used in removing the densely adherent membrane from the compressed lung.

a period of 7 days. The first 4 days after admission the soldier was given 5,000 units of penicillin every 3 hours then by some misinterpretation of orders, the drug was discontinued and it was never reconstituted.

At operation under intratracheal gas-oxygen-ether anesthesia, through a posterolateral incision with resection of a 3 centimeter section of the 7th rib the pleural cavity was found to be filled with organizing clots of purulent exudate with multiple empyema pockets. The entire lung was collapsed against the mediastinum and enveloped by a thick 4 millimeter tough and very adherent membrane. A clean line of cleavage could not be identified but by slow and tedious sharp and gauze dissection, the greater thickness of this restricting sheet was stripped from the visceral pleura, although a thin membrane was too adherent to be separated except by removing small segments with the visceral pleura. However 90 per cent re-expansion was obtained after inflating the lung with 8 millimeters of positive pressure. A No. 26 catheter was placed in the 2d interspace anteriorly and a No. 32 catheter in the 7th interspace in the posterior axillary line. Before closing in layers with interrupted silk sutures, an intercostal nerve block with novocain was effected of the 3d, 4th, 5th, 6th and 7th nerves.

Prior to the operation blood was started in the right ankle and the left arm 1,000 cubic centimeters, 500 cubic centimeters of plasma and 500 cubic centimeters of 5 per cent glucose were given during the operation. Bronchoscopic aspiration was thought unnecessary postoperatively as the bronchial system was

Fig. 4 Lung completely freed and inflated. Re-expansion of the lung following extirpation of the constricting capsule.

Fig. 5. a, The areas of increased density proved to be multiple pockets of empyema. The entire lung field is further obscured by organizing fibrinous exudate. b, Re-expansion

of lung after decortication. The shadow along periphery, usually termed thickened pleura, actually is an organized membrane over parietal pleura that need not be extirpated.

relatively dry, having been successfully aspirated by a long tracheal catheter.

The postoperative course was without mishap. Both catheters were removed within 16 days without further pocketing or the necessity of aspiration. Twenty-eight days after operation an x-ray film (Fig. 5b) showed satisfactory re-expansion of the lung. Patient was discharged to class B duty¹ 42 days after operation.

We assumed we were protected by penicillin but inadvertently this patient did not receive any penicillin 4 days prior to the operation or any afterward. This case represents supportive evidence that the operation is physiologically sound. Irrespective as to whether penicillin has any specificity against the infecting organism we recommend the continuance of its use.

CASE 3. This infantryman was wounded by small arms fire sustaining a penetrating wound of his right chest. Seven hours after injury a thoracotomy was done in a forward hospital. The right diaphragm was found to have been perforated and the dome of the liver was lacerated. No attempt was made to suture the liver, but subdiaphragmatic drainage was effected through a subcostal flank incision. The diaphragm was closed, then the pleural cavity was closed without drainage.

Class B duty includes any type of duty except combat.

The patient was admitted to a general hospital 8 days afterward, dyspneic, slightly cyanotic, with a temperature of 102.8 degrees F. and signs and symptoms of fluid in the right chest. After aspiration a tube was placed in the 6th interspace in the posterior axillary line; there was obtained foul smelling bile stained exudate from which gram-negative bacilli were cultured. There was also drainage of a similar character from the subdiaphragmatic stab wound. X-ray examination (Fig. 6a) showed the diaphragm to be fixed and elevated. Temperature elevation continued. Penicillin and sulfathiazole were used interchangeably and together for a period of 10 days. The lung was completely collapsed and another fluid level was detected about the drainage tube. For that reason 8 days after admission thoracotomy and decortication were done with resection of the 5th rib in the posterior axillary line. The chest cavity was filled with (Fig. 6b) yellow, bile stained, foul smelling exudate intermixed with flaky, partly organized fibrinous masses of pus. The lung was compressed into a small area in the posterior gutter area. The membrane which was removed from the visceral pleura with difficulty measured 2 to 3 centimeters in thickness. Oozing from the pleural surface was considerable. Transfusions of 1,300 cubic centimeters of blood and 1,000 cubic centimeters of plasma were necessary to sustain the patient. Blood pressure to 90/60 throughout the operation. Numerous leaks in the lung were detected after its reinflation. These were closed with interrupted silk sutures, but to compen-

Fig. 6. a, The diaphragm is markedly elevated and the remainder of the right lung field is greatly obscured by pus and organized hemothorax. b, Bile stained, partly organized, purulent exudate overlying the membrane like capsule, which is compressing the lung to the posterior gutter. c, Six weeks after operation, shows satisfactory re-expansion of the lung. The patient was asymptomatic; however the diaphragm remains elevated. This, seemingly has no bearing on the convalescence of this type of case.

Fig. 6b

safe for any unrecognized leakage, two catheters were placed anteriorly—one in the 2d interspace in the midclavicular line, one in the 4th interspace in the

anterior line, and also one in the 7th interspace in the posterior axillary line. Bronchoscopic aspiration was performed postoperatively for excessive tenacious bronchial secretion. Oxygen was started as he returned to the ward. It should be noted that a communication through the diaphragm 2 centimeters in diameter in the anterior medial area, could be felt, but it was thought the surrounding tissue would not lend itself to plastic repair. A large catheter was placed in the subcostal sinus beneath the diaphragm; this also was connected to a water-seal jug. It was interesting to observe respiratory motion of the water column from this catheter.

Six weeks after operation x ray (Fig. 6c) shows that the diaphragm remains elevated and adherent laterally. Fifty three days after decortication the patient was asymptomatic and was discharged to class B duty.

The infecting organism was a gram negative bacillus. Theoretically penicillin is ineffective against such bacteria. Sulfathiazole was also given though we fully realized drugs of the

sulfa derivation cannot effect bacteria in the presence of pus. More for luck and for lack of courage not to give them both were used. However, we believe they played no rôle in the recovery of this patient. True enough the diaphragm did remain elevated and a lateral shadow was apparent when the patient was discharged. All of which is accountable because of not decorticating the diaphragmatic and parietal pleura. To decorticate the parietal pleura is totally unnecessary. As for decorticating the diaphragm the objections are (a) it prolongs the operation on a seriously ill patient (b) the surface oozed more freely than does the visceral pleura (c) all patients with postoperative high fixed diaphragms seemingly get well satisfactorily soon without this added procedure.

CASE 4. The patient was wounded in action by a shell fragment 7 hours before admission to an evacuation hospital. He had multiple wounds of his arms, right thorax, and abdomen. Resuscitation was adequately carried out prior to debriding the wounds following which an exploratory thoracotomy was performed and then a laparotomy. Through a right thoracotomy approach the diaphragm was repaired. Laparotomy was performed through a separate incision (intra-abdominal viscera were found to be intact). The foreign body was removed from the right retroperitoneal tissue. He was evacuated to a general hospital 2 days later in fair condition. According to the admission note there was considerable subcutaneous emphysema in the right thoracic and upper abdominal regions. Aspiration of the chest revealed 350 cubic centimeters purulent, odorous fluid which was tinged with blood and 200 cubic centimeters of air. X-ray examination (Fig. 7) showed the lung 75 per cent collapsed surrounded by a shadow which was thought to be organizing hemothorax, and also an elevation of the right diaphragm. Repeated aspirations were carried out although only a small amount of thick exudate was obtained. A subdiaphragmatic abscess was found and drained through the bed of the resected 12th rib. However this did not alleviate the temperature elevation and symptoms of toxicity.

Two weeks afterward a decortication was done and 1000 cubic centimeters of thick, odorous exudate was removed. There was found multiloculated empyema rather compartmented in balls of pus. The entire upper lobe was held fast and further compressed by a thick capsule. The fibrous layer on the visceral pleura was stripped away. Bleeding was free. Unfortunately the pleura was torn in the removal of this capsule. Three catheters were used after operation to drain the air and the resultant exudate. Intercostal nerves were blocked inferiorly. The wound was then closed with interrupted sutures of

Fig. 7. Partial collapse of the right lung from what proved to be a multiloculated empyema overlying a thick fibrous membrane. There is elevation of the diaphragm from a fluid and gas containing pocket, which proved to be a subphrenic abscess.

silk. One thousand cubic centimeters of blood and a liter of 5 per cent glucose were necessary to support the patient during the operation. A moderate amount of bloody exudate was aspirated through a bronchoscope at the end of the operation. After he was returned to the ward a Wangenstein suction was applied to the anterior catheter in the 2d interspace—a commercial type of apparatus being used.

The postoperative course was stormy. Suddenly he was found to be unusually dyspneic and it was then discovered that the suction apparatus was improperly connected, thus creating an artificial hydrothorax. The chest was immediately aspirated as oxygen under positive pressure was given but the lung did not re-expand immediately. However it did re-expand gradually and drainage from the posterior catheter continued for a period of 33 days. The temperature ranged from 100 to 104 degrees F. 14 days postoperatively. He was discharged to the Zone of the Interior 37 days postoperatively. There was no evidence of repocketing. His general condition was excellent and the lung had re-expanded to an estimated 85 per cent of normal. (Postoperative x-ray films are not available.)

In patients that have a traumatized compressed lung for a period of 3 weeks or longer it is noted that the lungs are nonresilient to re-expansion and any added difficulty preventing re-expansion serves as a definite hazard.

Fig. 8. a. Almost complete collapse of the right lung from multiloculated empyema and clotted hemothorax. b. Twenty-seven days after operation, the lung is re-expanded.

Although the diaphragm is slightly elevated. The three foreign bodies which are not removed at operation are now visible.

In this case an artificial hydrothorax was produced which added greatly to his period of convalescence. It should be emphasized that only simple home made suction apparatus should be used in these cases. We are opposed to the use of any complicated apparatus as such frequently confuse even the expert attendant.

CASE 5. This patient was injured by a mortar shell which resulted in a sucking right hemothorax, rigid abdomen and a compound comminuted fracture of the right radius and ulna. He was admitted to an evacuation hospital 7 hours after wounding. His condition was fair but he was given 500 cubic centimeters of blood and 500 cubic centimeters of plasma prior to and during débridement of wounds and exploratory laparotomy. The sucking chest wound after débridement was closed without drainage to the pleural cavity; the laparotomy revealed no visceral injury. There was no record of preoperative aspiration. After operation he was aspirated of air anteriorly and posteriorly. Intercostal nerve block, 4th through 11th nerves was effected. The following day 1000 cubic centimeters of air and 400 cubic centimeters of fluid were withdrawn. Two days after operation a temperature of 103 degrees F was recorded. Repeated aspirations yielded a small amount of turbid exudate at three different sites and only 100 cubic centimeters of air. Roentgenogram (Fig. 8a) revealed the lung partially collapsed and obscured by a dense thickness which was thought to be clotted hemothorax. Blood

penicillin and other supportive measures were continued. From the aspirated fluid hemolytic streptococci were cultured. Further aspirations were successful. The patient's general condition was growing worse. In view of the findings it was apparent we were dealing with a multiloculated empyema associated with organizing hemothorax. Any temporizing such as tube drainage would only prolong his hospitalization—first that reason laceration was performed 14 days after wounding.

The 8th rib was resected in the posterior axillary line (the incision was made to usually not avoid the right chest wound). The chest cavity was filled with multiple compartment containing non-odorless, gelatin like fibrin and pus. The lung was 80 per cent collapsed and held down by a well organized sheet of fibrinous exudate. This constricting band was rather easily peeled thus allowing the lung to re-expand completely. Three small foreign bodies were known to be located in the base of the lower lobe, which was the site of a large hematoma. Due to the fact that these foreign bodies could not be palpated, it was felt unwise to attempt their removal. Three catheters were placed: two anteriorly and one in the posterior axillary line. Penicillin (100,000 units) was then introduced into the pleural cavity. Bronchoscopic aspiration at the end of the operation yielded a moderate amount of mucus. One thousand cubic centimeters of blood were given during the operation.

The postoperative course was most satisfactory. A temperature of 99 degrees F was the highest re-

a

b

Fig 9. a. The left chest is obliterated by fluid and a "thickened pleura." At operation it was disclosed to be a sheet, 2 to 6 centimeters in thickness, of organizing exudate. b. Roentgenogram which was taken 4 weeks fol-

lowing operation, shows satisfactory re-expansion of the lung. The shadow which was present at the base was attributed to the remaining fibrinous layer on the diaphragm and parietal pleura.

corded after operation. Catheters were all removed by the 7th postoperative day. Later thoracenteses found no blood fluid or air. At the time of discharge (Fig 8b) the lung had completely re-expanded but the right diaphragm remained elevated and the pleura was thickened at the base. He was discharged 27 days after operation.

This case illustrates early decortication for multilocated empyema and organizing hemothorax with compression of the apex of the lung. The relative ease with which the organized membrane stripped from the visceral pleura is remarkable and may be attributed to early operation without preliminary drainage. It is thought that this method of management should be adopted in those cases of empyema in which decortication is indicated.

CASE 6 This soldier was treated in an evacuation hospital for a period of 10 days following chills, fever and pain in the left chest. Diagnosis there was lobar pneumonia. He did not respond to penicillin therapy. Therefore he was transferred to the medical service of a general hospital. The patient appeared acutely ill with a respiratory rate of 26 and a temperature of 102.4 degrees F. There was dullness over the entire left chest area (Fig 9a) with diminished tactile fremitus. After numerous attempts to aspirate the fluid, 500 cubic centimeters of greenish colored fluid were obtained only from the 5th intercostal space in the midaxillary line. There 50,000 units of penicillin

were injected into the pleural cavity. Cultures showed a few hemolytic streptococci. The patient was transferred to the surgical service 3 days after admission.

Repeated chest taps, local anesthesia being used, located purulent exudate in the 5th intercostal space in the anterior axillary line at which site a catheter was placed through a trocar and connected to a water seal jug. In the 9th interspace in the posterior axillary line fluid of a different character was obtained, a greenish thin transudate. A second catheter was inserted into this pocket. Further taps did not yield additional fluid.

The catheters ceased to drain after 3 days. Knowing that multiple pockets of pus were present, the problem of individually draining them seemed impractical. Therefore we thought the patient was a candidate for decortication.

Five days after institution of catheter drainage thoracotomy with decortication under endotracheal gas-oxygen-ether anesthesia was done. A posterolateral incision with resection of the 7th rib was used. In the posterior gutter the lung was tenaciously adherent and collapsed against the chest wall. Multiple thick walled pockets of cheese like material were ruptured and evacuated. This brought us down on the thick adherent capsule that held the lung compressed. With considerable difficulty the visceral pleura was eventually denuded of this sheath of organizing exudate measuring 2 to 6 centimeters in thickness. Under positive pressure the lung was inflated to normal expansion. Bleeding was very annoying over the entire surface of the visceral pleura.

Fig. 8. a Almost complete collapse of the right lung from multiloculated empyema and clotted hemothorax. b. Twenty-seven days after operation, the lung is expanded,

although the diaphragm is slightly less fixed. The three foreign bodies which were not removed at operation are now visible.

In this case an artificial hydrothorax was produced which added greatly to his period of convalescence. It should be emphasized that only simple home made suction apparatus should be used in these cases. We are opposed to the use of any complicated apparatus as such frequently confuse even the expert attendant.

CASE 5. This patient was injured by a motor car which resulted in a sucking right hemothorax, right abdomen and a compound comminuted fracture of the right radius and ulna. He was admitted to a local hospital hours after wounding. His condition was fair but he was given 500 cubic centimeters of blood.

On the first and 500 cubic centimeters of plasma were given and during debridement of wound an exploratory laparotomy. The sucking chest wound after debridement was closed without drainage to the pleural cavity. The laparotomy revealed no visceral injury. There was no record of preoperative pirith.

After operation he was a pirated of air anteriorly and posteriorly. Intercostal nerve block with through eighth nerves was effected. The following day 1000 cubic centimeters of air and 400 cubic centimeters of fluid were withdrawn. Two days after operation a temperature of 103 degrees F was recorded. Repeated aspirations yielded a small amount of turbid exudate at three different sites and only 100 cubic centimeters of air. Roentgenogram (Fig. 8a) revealed the lung partially collapsed and obscured by a dense thickness which was thought to be clotted hemothorax. Blood

penicillin and other supportive measures were continued. From the aspirated fluid hemolytic streptococci were cultured. Further pirations were unsuccessful. The patient's general condition was growing worse. In view of the fact that it was apparent we were dealing with a multiloculated empyema associated with organizing hemothorax, any temporary such a tube drainage would only prolong his hospitalization—after that reason decortication was performed 14 days after wounding.

The 8th rib was resected in the posterior axillary line (the incision was made unusually low to avoid the sigmoid chest wound). The chest cavity was filled with multiple compartment containing 500 cc. of 10% gelatin, 10 cc. of fibrin and pus. The lung was 80 per cent collapsed and held down by a well organized sheet of fibrinous exudate. This contracting band was rather easily peeled thus allowing the lung to re-expand completely. Three small foreign bodies were known to be located in the base of the lower lobe which was the site of a large hematoma. Due to the fact that these foreign bodies could not be palpated, it was felt unwise to attempt their removal. Three catheters were placed in anteriorly and one in the posterior axillary line. Penicillin (100,000 units) was then introduced into the pleural cavity. Bronchoscopic aspiration at the end of the operation yielded a moderate amount of mucus. One thousand cubic centimeters of blood were given during the operation.

The postoperative course was most satisfactory. A temperature of 99 degrees F was the highest re-

Fig 9. a, The left chest is obliterated by fluid and a "thickened pleura." At operation it was disclosed to be a sheet, 2 to 6 centimeters in thickness, of organizing exudate. b, Roentgenogram which was taken 4 weeks fol-

lowing operation, shows satisfactory re-expansion of the lung. The shadow which was present at the base was attributed to the remaining fibrous layer on the diaphragm and parietal pleura.

corded after operation. Catheters were all removed by the 7th postoperative day. Later thoracenteses found no blood, fluid or air. At the time of discharge (Fig 8b) the lung had completely re-expanded but the right diaphragm remained elevated and the pleura was thickened at the base. He was discharged 27 days after operation.

This case illustrates early decortication for multiloculated empyema and organizing hemothorax with compression of the apex of the lung. The relative ease with which the organized membrane stripped from the visceral pleura is remarkable and may be attributed to early operation without preliminary drainage. It is thought that this method of management should be adopted in those cases of empyema in which decortication is indicated.

CASE 6 This soldier was treated in an evacuation hospital for a period of 10 days following chills, fever and pain in the left chest. Diagnosis there was lobar pneumonia. He did not respond to penicillin therapy. Therefore, he was transferred to the medical service of a general hospital. The patient appeared acutely ill with a respiratory rate of 26 and a temperature of 102.4 degrees F. There was dullness over the entire left chest area (Fig 9a) with diminished tactile fremitus. After numerous attempts to aspirate the fluid, 500 cubic centimeters of greenish colored fluid were obtained only from the 5th intercostal space in the midaxillary line. There 50,000 units of penicillin

were injected into the pleural cavity. Cultures showed a few hemolytic streptococci. The patient was transferred to the surgical service 3 days after admission.

Repeated chest taps, local anesthesia being used, located purulent exudate in the 5th intercostal space in the anterior axillary line at which site a catheter was placed through a trocar and connected to a water seal jug. In the 9th interspace in the posterior axillary line fluid of a different character was obtained, a greenish thin transudate. A second catheter was inserted into this pocket. Further taps did not yield additional fluid.

The catheters ceased to drain after 3 days. Knowing that multiple pockets of pus were present, the problem of individually draining them seemed impractical. Therefore, we thought the patient was a candidate for decortication.

Five days after institution of catheter drainage, thoracotomy with decortication under endotracheal gas-oxygen-ether anesthesia was done. A posterolateral incision with resection of the 7th rib was used. In the posterior gutter the lung was tenaciously adherent and collapsed against the chest wall. Multiple thick walled pockets of cheese like material were ruptured and evacuated. This brought us down on the thick adherent capsule that held the lung compressed. With considerable difficulty the visceral pleura was eventually denuded of this sheath of organizing exudate measuring 2 to 6 centimeters in thickness. Under positive pressure the lung was inflated to normal expansion. Bleeding was very annoying over the entire surface of the visceral pleura.

from which the adherent sheath had been extirpated. Several rents in the visceral pleura were sutured with silk and tested under water for leakage. Closure was made in anatomical layers with silk sutures. Mushroom catheters were placed in the 2d interspace anteriorly and in the 7th interspace in the postero-axillary line. The patient received 1000 cubic centimeters of blood and 1000 cubic centimeters of 5 per cent glucose during and immediately after operation. Following the operation bronchoscopic aspiration was performed for excessive bronchial secretion.

Four days later the anterior catheter was removed. Progress seemed satisfactory. The posterior catheter was removed on the 7th day. No further pocketing developed. X-ray examination (Fig. 9b) showed good expansion of the lung 4 weeks after operation.

Six weeks after operation convalescence was essentially complete with patient ready for discharge to class B duty.

This postpneumonic sequel is uncommon since the advent of chemotherapy. It was interesting to note that the pathology encountered was not grossly different from that in the multiloculated post-traumatic empyema. The capsule however was more tenaciously attached to the visceral pleura and there was a definite increase in the bleeding from the decorticated pleural surface.

SUMMARY

1. The indications for radical and conservative management in acute empyema are briefly discussed.

2. Certain points in the technique of pulmonary decortication for acute empyema are emphasized.

3. Six cases are presented in which thoracotomy with evacuation of the pleura and pulmonary decortication was employed in acute empyema. In one of these cases the empyema was a postpneumonic infection. All others were post-traumatic infections.

4. Early operation without preliminary drainage seems advisable when the indications for the radical management are present.

5. Penicillin was not used in 1 case and was of questionable value in others but its routine use is recommended.

CONCLUSION

Early radical surgical attack in selected cases of acute empyema will greatly reduce the incidence of chronic empyema and "pulmonary cripples."

OSTEOGENIC SARCOMA

II Roentgenographic Interpretation of Growth Patterns in Bone Sarcoma

IAN MACDONALD M D and JOHN W BUDD M D Los Angeles, California

THE speech and reports of roentgenologists when concerned with bone tumors are studded with such words as typical 'characteristic' and even diagnostic. Sutherland has stated that given adequate technique the same information that is available in the cut section of tissue prepared for microscopic study can be obtained from the roentgenogram. More recently McNattin relying exclusively on roentgenograms as an accurate method of diagnosis has proposed that the primary treatment of bone sarcoma should be by massive doses of x radiation even to the point of necrosis.

It should be emphasized that the authors of this essay are not diagnostic roentgenologists but we believe that radiographic arbiters such as Sutherland and McNattin ascribe to bone tumors a fixity of roentgenographic pattern that simply does not exist. Our thesis is that the roentgen ray study of bone tumors is an interpretation of the activity of the neoplasm and equally of the character of the stromal response. Thus the appearance of a bone tumor at a given time depends upon the balance between neoplastic activity (osteolysis) and the degree of cortical and medullary reaction (sclerosis) as well as the absence or extent of ossification and calcification. The sunray appearance of many osteosarcomas may be due either to new bone formation or calcification in parallel striae and may be seen in chondrosarcoma and even in neoplastic metastatic lesions of bone. Even Codman's time honored reactive triangle may be seen in chronic periostitis. In short typical roentgenographic features are a reflection of growth characteristics rather than an indication of tumor types *a kinetic rather than a static concept*.

The observations presented here are part of a study of 118 cured cases of bone sarcoma.

From the School of Medicine University of Southern California

and a smaller number of uncured cases from the Registry of Bone Sarcoma of the American College of Surgeons. The primary objective in the review of these cases was to determine whether there were special features in the natural history and histopathology of the cured cases sufficiently distinctive to account for their curability. Such features have been established and were the subject of another communication but certain general features of histopathology and nomenclature are highly pertinent here.

Of first importance is the definition of terms. The expression osteogenic sarcoma is used widely and interchangeably to signify a malignant tumor originating in or producing bone. We accept the term as indicating an origin in bone but not necessarily producing bone a definition which is also approved by Ewing and other writers. Osteogenic sarcoma then becomes a generic name for those sarcomas arising in the connective tissues of bone distinguishing this numerically large group from those of less frequent incidence arising in hematopoietic endothelial and adipose tissue elements of the medulla.

Two of the connective tissue sarcomas of bone are well known those predominantly producing bone and cartilage osteosarcoma and chondrosarcoma. Our study of the cured cases emphasized the importance of the third member of the group which is fibroblastic in nature. The proposed division of the connective tissue sarcomas is shown in the classification presented here in which bone producing sarcomas are designated as osteosarcoma a proper etymological expression to match the terms chondrosarcoma and fibrosarcoma. The roentgenologist may make a diagnosis of osteogenic sarcoma with reasonable expectation of verification if there is evidence of a cortical malignant tumor. This study has led us to the

Fig. 1. Left: Metastatic adenocarcinoma simulating primary osteogenic sarcoma.
Fig. 2. Chondrosarcoma, early peripheral. () B.S.R. N 5

conclusion that radiographic criteria are highly unreliable in attempting a more accurate differential diagnosis of osteogenic sarcomas.

The prognostic importance of differentiating the three connective tissue sarcomas however is shown in Table I. Osteosarcoma or true bone producing sarcoma is a highly lethal disease represented by less than 12 per cent of the cured while it accounts for 40 per cent of the fatal cases. (Table I). Fibrosarcoma is the

(Numbers in parentheses refer to schematic chart) Fig

least malignant member of the group accounting for 37 per cent of the cured but only 15 per cent of the uncured patients. Chondrosarcoma seems to occupy a median position between these two extremes.

An interpretation of the growth pattern of bone tumors by experienced roentgenologists, according to a kinetic concept should differentiate with almost complete accuracy between benign and malignant tumors. While the differential diagnosis of bone sarcoma into tumor types by radiographic methods seems

MODIFIED CLASSIFICATION OF BONE TUMORS

Type of tumor	Malignant	Benign
Connective	Osteosarcoma Chondrosarcoma Fibrosarcoma	Osteoma Chondroma
Undetermined	Malignant giant cell tumor	Benign giant cell tumor Epiphyseal chondromatous giant cell tumor
3. Endothelial	(a) Angiosarcoma (b) Diffuse endothelioma (Ewing sarcoma)	(a) Pilexiform angioma (b) Cavernous angioma
4. Hematopoietic	() Erythrocytoma (b) Myelocytoma, myeloma () Lymphocytoma (d) Reticulocytoma

Fig. 4. Chondrosarcoma, peripheral (3) B.S.R. No. 777

to us more speculative the material reviewed permits the recognition of features commonly seen in the connective tissue sarcomas

Osteosarcoma arises in the metaphysis and may be predominantly sclerosing or osteolytic. The sclerosing form is more common and may be peripheral or central in origin. The peripheral sclerosing is the classical type in which the tumor early elevates the periosteum usually with dense radiating striae and Codman's reactive triangle. With continued growth there is progressive sclerosis of the cortex and medulla and soft tissue extension in advanced cases. The only sign of central sclerosing osteosarcoma may be a dense obliteration of the cortical striae while secondary destruction in the medulla produces a mottled appearance.

The pure osteolytic form of osteosarcoma is the old telangiectatic bone aneurysm and represents a rare and extremely anaplastic form. There is irregular expansile destruction of the cortex little or no periosteal reaction. There may be early perforation and bulky soft tissue masses invasion of the epiphysis and adjacent joint.

Chondrosarcoma arises in the ends of the diaphyses of long bones and vertebrae. There are two well defined forms peripheral and central. In the peripheral an irregular productive periosteal growth is the earliest stage. Calcification is extremely common in chondrosarcoma and is responsible for its radiopacity. It may early perforate the periosteum and produce bulky lobulated soft tissue tumors or blotchy irregular masses.

TABLE I — PERCENTAGE INCIDENCE OF FORMS OF OSTEOGENIC SARCOMA IN 5 YEAR SURVIVALS AND IN NONSURVIVALS

<p>LOCATION Most cases in metaphysis. Most common lower limb, upper limb. Usually in bone may involve epiphysis and adjacent joint.</p>	<p>LOCATION Is made of shafts of long bones. Part bone and periosteum.</p>	<p>LOCATION Any part of long bones epiphysis included. Fragments form of nature of flat bones.</p>

Fig. 11 Roentgenographic interpretation of evolution of osteogenic sarcoma.

of calcifying neoplasm. Calcification may also occur in linear striated style simulating peripheral sclerosing osteosarcoma. The central type of chondrosarcoma often produces irregular areas of rarefaction usually with adjacent reactive sclerosis forming a shell around the tumor. Eroded areas may appear cystic and resemble fibrosarcoma. Sclerosis and calcification may predominate in the central type with dense ivory like obscuration of architecture.

Fibrosarcoma may arise in any part of a long bone epiphyses included. It is a frequent form of sarcoma of flat bones. The most common form is the osteolytic. In its early stage its origin may be evident as medullary cortical or periosteal. It may enlarge to form a single predominantly destructive lesion with little or no reactive sclerosis or periosteal thickening. They are most commonly non expansile tumors. Radiographic evidence of extension is frequently that of an irregular spotty osteolytic process with or without sclerosis of adjacent bone. Multiple cyst like areas are not uncommon and should not be confused with giant cell tumors for the outline of the pseudocystic areas is irregular and there is usually adjacent progressive osteolysis. The microscopic picture is usually entirely comparable to that seen in soft tissue sarcomas. These forms are frequently slow or even indolent in their growth and 5 year cures have been obtained by amputation after repeated local operations.

There is an advanced diffuse osteolytic form of fibrosarcoma less common which affects one third or more of a large bone in which there are linear and circumscribed areas of rarefaction with intervening strands of sclerosing bone. The result is a ragged moth eaten appearance which may simulate Ewing's sarcoma.

In any soft tissue fibrosarcoma ossification may occur. Most ossifying fibrosarcomas in bone in the past have been diagnosed as osteosarcoma. Ossification in fibrosarcoma of bone results in a sclerosing lesion which may be difficult to differentiate from osteosarcoma or sclerosing chondrosarcoma. Ossification may occur only in parts of a fibrosarcoma with other areas of osteolytic character making the diagnosis more plausible.

The simulation of primary bone tumors by metastatic lesions has been repeatedly observed by us in the past 4 years. One of the most striking of these is that shown in Figure 1. This patient's past symptom was that of pain in the thigh just above the knee. The x ray films were diagnosed without equivocation by three roentgenologists as typical osteosarcoma.

When a biopsy was obtained the microscopic features were those of an adenocarcinoma metastatic from the prostate gland. Since this rather astonishing discovery metastatic lesions from the stomach ovary lung and breast have been observed as producing essentially the same picture.

SUMMARY

The roentgenographic interpretation of bone tumors is properly a study of patterns of neoplastic activity and the character of the stromal response—a kinetic rather than a static concept. The roentgenologist can determine with a high degree of accuracy the benignancy or malignancy of a given lesion. Further differential diagnosis of tumor types by radiographic methods must be regarded as speculative. Metastatic lesions may simulate perfectly the appearance of primary sarcoma of bone. Microscopic study of tissue obtained by open biopsy remains as the most essential single diagnostic method in tumors of bone. Ewing's sarcoma (endothelial myeloma) is a notable exception for in tumors presenting

suggestive evidence of this lesion a therapeutic test with small doses of x radiation is a valuable diagnostic aid. In general formal biopsy of bone tumors should precede the institution of any therapeutic program either surgical or radiological. All reliable evidence fails to establish any hazard in open or needle biopsy of bone sarcomas. To employ intensive irradiation of bone lesions on roentgenographic evidence alone is an unwarranted intellectual obeisance to a fallible diagnostic measure.

ACQUIRED ESOPHAGOTRACHEOBRONCHIAL FISTULA

O THERON CLAGETT M D F.A.C.S JOHN H PAYNE, M D and
HERMAN J MOERSCH M D Rochester Minnesota

ACQUIRED esophagotracheobronchial fistulas are of infrequent occurrence and have a poor prognosis and a high mortality rate. These fistulas are most often associated with malignant disease of the esophagus or trachea and occur as a late or terminal complication of the underlying pathologic process.

One must have a clear concept of the anatomic relation of the esophagus to the trachea in order to appreciate the ease with which these fistulas may occur. The esophagus begins at the level of the cricoid cartilage and descends in front of the vertebral column through the superior and posterior mediastinum. It passes through the diaphragm and ends at the cardia of the stomach. The trachea lies just anterior to the upper portion of the esophagus, being separated from it by a few lymph nodes which are most numerous in the region of the bifurcation. As the esophagus descends in the thorax it curves to the left and is crossed by the left main bronchus. It then passes to the right and behind the arch of the aorta and descending in the posterior mediastinum lies to the right of the thoracic aorta. Lower in the thorax it passes to the left and anterior to the aorta. Since the trachea and the upper part of the esophagus lie in such close apposition it is easy to understand how a pathologic process of one organ may spread and involve the other organ secondarily.

CAUSES

There are five main causes of esophagotracheobronchial fistulas. In order of their frequency they are as follows:

1. Malignant disease of the esophagus
2. Infectious disease of the esophagus, trachea or pleura
 - A. Tuberculosis
 - B. Syphilis
 - C. Fungus infections
 - D. Suppurative esophagitis
 - E. Nontuberculous empyema
3. Traumatic injuries of the esophagus
4. Esophageal diverticula
5. Esophagomalacia

Carcinoma of the esophagus is the most frequent cause of fistula formation. Ewald stated

From the Divisions of Surgery and Medicine, Mayo Clinic.

that 50 per cent of carcinomas of the middle third of the esophagus are associated with fistula. Tinney and one of us (H J M 15) reported a series of 39 cases of fistula in 14 cases (36 per cent) the fistula was associated with carcinoma of the esophagus. In 4 cases (10 per cent) the fistula was the result of a malignant lesion which arose in the thyroid in the trachea or in the bronchus.

Lymphoepithelioma of the lower part of the pharynx may also cause fistula formation. Boyd and Goldbloom have reported a case of this nature.

Infectious diseases of the esophagus, trachea, pleura or adjacent lymph nodes are the second most common cause of fistula. Tuberculosis is a frequent etiologic factor. It may cause fistula formation in several different ways. Heddaeus and Riviere expressed the belief that fistulas may arise from a breaking down of caseous lymph nodes which ulcerate into the trachea and esophagus. In Pachnos' opinion tuberculosis causes an esophageal ulceration with subsequent perforation. Kelly and Henderson expressed the belief that tuberculous lymph nodes may perforate into the trachea and esophagus as the result of a slow process of ulceration on the outer walls of these structures. In their opinion also tuberculous lymph nodes in healing may cause the formation of traction diverticula which enlarge, ulcerate, and finally rupture to form a fistula. Tuberculous ulcers of the trachea or bronchi may perforate into the esophagus and form a fistula. Tuberculous empyema of long standing occasionally will cause an esophagobronchial fistula to form.

Syphilis may cause the formation of esophagobronchial fistula in two ways. It may give rise to gummas in the esophagus or air passages, which eventually ulcerate, perforate, and form fistulas. Bucher and Ono reported 13 cases of this sort. Syphilis also may cause fistula formation through the development of an aneurysm which from prolonged pressure, may produce an esophagotracheal fistula. Dörner has reported a case of this nature.

Actinomycosis is a rare cause of fistula formation but Vinson and Sutherland reported such a case. The patient lived for 20 years after the development of the fistula.

Fig. Fistulous tract between the right main bronchus and the esophagus. Its relation to the azygos vein and to the superior vena cava and the trachea is all seen. Insets show the incision, a larger view of the fistula, the fistulous tract ligated and the reinforcement of the ligated ends of the fistulous tract with pleura.

Phlegmonous or suppurative esophagitis may give rise to a fistula. Such an inflammatory process may result from the action of some corrosive chemical that has been swallowed or it may be secondary to a pulmonary or pleural infection of long standing. Berman and Walters reported a case in which a fistula was due to nontuberculous empyema. In cases of nontuberculous empyema, fistulas are more likely to occur when a hard rubber tube has been used to drain the pleural space for a prolonged period than under other conditions.

Traumatic perforation of the esophagus, either by some foreign body or by instrumentation may give rise to a fistula. Rarely diseased bone in an adjacent vertebra may cause fistula formation. Judd, Havens, and two of us (O.T.C. and H.J.M.) reported a case in which fistula was due to a bullet wound. Surgical treatment of the fistula was successful. Murtagh and Tyson have reported a fistula due to a piece of bone lodging in the anterior esophageal wall. The fistula healed promptly and completely on removal of the bone.

Esophageal diverticula. whether they are of the congenital or of the acquired traction type, occasionally cause the formation of fistulas. These arise because of inflammation and ulceration of the diverticulum with secondary perforation into the trachea or bronchi. Occasionally the diverticula may cause a mediastinal abscess which can rupture into a bronchus, thereby forming a fistula.

Davidson and Mills stated that esophagomallacia is a rare cause of esophagobronchial fistula. This occurs as an agonal manifestation in cases of cerebral disease, as a result of digestion of the esophageal walls by gastric contents.

SYMPTOMS

Although as a rule congenital tracheo-esophageal fistulas manifest their presence at once by a definite group of symptoms, acquired fistulas may be present for varying periods before they produce symptoms. There is generally a history of varying degrees of dysphagia gradually increasing in severity. Then suddenly cough develops as well as dyspnea when the patient eats

and he raises purulent sputum and occasionally blood. At first these symptoms follow the ingestion of liquid foods but later on they may follow the ingestion of either solid or liquid food. Lukens and Ono stated that coughing and dyspnea are most likely to occur when the patient is on his left side in an upright position or leaning forward when he swallows. Allen has reported 2 cases (proved roentgenologically) in which a fistula was present but the patient had not had any symptoms. If one suspects the presence of an esophagotracheobronchial fistula, a bronchoscopic and an esophagoscopic examination should be performed in an endeavor to visualize the fistulous opening. A roentgenoscopic examination of the esophagus should also be performed after the patient has swallowed a small quantity of radiopaque oil. These patients should not be given barium to swallow as it is very irritating to the parenchyma of the lung whereas radiopaque oil is not.

TREATMENT

The treatment of esophagotracheobronchial fistula varies with the cause of the condition. When fistula arises from malignant disease there is really no treatment available, as the fistulas are terminal complications and the patients will die of the malignant lesion regardless of their treatment. Some of the other types of fistula though, are amenable to various forms of therapy. Clerf, Cooley and O Keefe have reported 2 cases in which esophagotracheal fistula was successfully treated by the application of crystals of sodium hydroxide. These crystals were fused on an applicator and pressed against the fistula for 3 minutes. This procedure was repeated 3 weeks later. Imbertoni has reported a case in which a high fistula was treated by excising the fistulous tract and closing the esophagus and trachea separately with interrupted sutures. This procedure was done by opening the anterior wall of the trachea and working on the fistulous opening in the posterior portion of the trachea. When these fistulas arise from empyemas, Cohen and Sindell advocated adequate drainage of the pleura and prolonged esophageal rest by the use of nasal tube feedings or gastrostomy feedings. This regimen is followed until the esophageal fistula has had adequate time to heal. Judd, Havens, and two of us (O.T.C. and H.J.M.) have reported a case in which a traumatic fistula was closed by excision of the fistula and individual closure of the esophagus and trachea with reinforcement of the suture lines by transplantation of the omohyoid muscle into the area.

REPORT OF CASE

We wish to report an additional case at this time in which the fistula was cured by operative intervention. The patient was a 59 year old white woman whose past history was negative except for a previous ectopic pregnancy that had been handled surgically. She had been in good health until 3 years before her admission to the Mayo Clinic. At this time a piece of meat had entered her trachea while she was eating, and, after this, a cough and an aching in her thorax developed. Six weeks later the meat was removed with a bronchoscope. She continued to cough, however, and on one occasion coughed up some pieces of calcified material. Her general health was good until one year prior to admission when progressive dysphagia developed. She soon noted severe paroxysms of coughing on taking liquids and regurgitated the liquids. She gradually lost 40 pounds (18.1 kgm.) At the time of our esophagoscopic examination she was found to have a sinus opening on the right lateral wall in the middle third of the esophagus. On bronchoscopy she was found to have a fistulous opening in the posterior wall of the right main bronchus through which esophageal secretion was coming.

Surgical exploration and closure of the fistula were advised. Preoperatively the patient was given 4 grams of sulfadiazine for 3 days. Transthoracic exploration was performed through a right posterior lateral incision, with removal of part of the sixth rib. Exploration of the esophagus and the lower part of the trachea disclosed a fistulous tract between the esophagus and the right main bronchus with many calcified lymph nodes in the region (Fig. 1). After the fistula had been dissected free, its esophageal end was ligated and turned in with interrupted catgut sutures. The bronchial end of the fistula was ligated separately and covered with pleura. The operative site was washed with saline solution and cephrin chloride (1:10,000) and 5 grams of sulfanilamide were dusted into the pleura. An intercostal catheter was inserted and the thorax was closed in layers. A Levine tube was passed into the stomach. The patient was given 80,000 units of penicillin intramuscularly each day for the first 11 postoperative days.

Jefunostomy feedings were begun through the Levine tube on the second postoperative day. The patient was allowed to drink clear liquids on the seventh day and the nasal tube was removed on the tenth postoperative day. A liquid diet then was begun and was gradually shifted over to a soft diet.

When the intercostal catheter was removed on the fourth postoperative day the lung remained well expanded. Thoracentesis was performed on the eighth and twelfth days and the patient was dismissed on the twenty first day in good condition. She was eating a soft diet and had not experienced any dysphagia, dyspnea, or coughing since the operation. The report of the pathologist on the specimen of tissue that was removed at operation was chronic inflammation and tuberculosis.

CONCLUSIONS

In conclusion one may see that these esophagotracheobronchial fistulas are a serious problem. In cases of fistula caused by some malignant condition the malignant disease itself is fatal. Those fistulas not associated with malignant conditions have a more hopeful outlook, although many of these patients, regardless of the cause of the fistula die of aspiration pneumonia, pulmonary abscess, or gangrene. This is especially true when

the fistulas are of considerable size. Direct surgical attack with closure of the fistula is feasible in some instances and some of the smaller fistulas may be treated adequately by the local application of crystals of sodium hydroxide.

GUNSHOT FRACTURES OF THE FEMORAL SHAFT

ERNEST A. BRAV M.D. F.A.C.S. Lieutenant Colonel, M.C., A.U.S., and
WILLIAM T. FITTS JR. M.D. Captain M.C. A.U.S. Philadelphia, Pennsylvania

A ZONE of Operations often affords an unusual opportunity of observing large numbers of compound fractures of the femoral shaft an injury not often encountered in civilian practice. This study is based upon a series of 82 cases received at a General Hospital during the campaign in North Burma from October 1943 to August 1944. It includes all complete compound fractures of the shaft, some of which were comminuted into the knee joint. Purely condylar fractures and those involving the head and neck are not included because they bring up different problems in management. This study has it is believed, enhanced value because the majority (85%) of the cases were Chinese soldiers, and it was possible for us to observe the patients from very shortly after their injury until the time when the end results could be ascertained with a reasonable degree of certainty. American soldiers, comprising 15 per cent of the series, were evacuated to the Zone of the Interior as soon as this could be done with safety. The mortality of the entire group was 4.9 per cent.

There was no significant variation in the side of the body concerned but the lower third of the shaft was most commonly involved. Approximately half of the cases were at this level and 8 of these, 10 per cent of the total, involved the knee joint. Middle third fractures are common in civilian practice, but accounted for only one sixth of this series. The remaining third were in the proximal portion of the shaft. A rifle bullet was said to be responsible for the wound in 51.62 per cent, of the cases, and shell fragments, most frequently from a mortar accounted for the others.

TIME OF ADMISSION

Sixty per cent of the patients were admitted within 48 hours of injury and of these two thirds were admitted within the first 36 hours. Early in the campaign there were delays in evacuation in a number of instances so that the average time interval was 5.9 days from injury to admission. Once the air evacuation system had been perfected, patients were received within an astonishingly brief time, especially when it is realized that a bitter haul for varying distances was required before a plane trip of 100 miles or more.

MANAGEMENT BEFORE ADMISSION

Debridement. It is our opinion that in a great majority of patients the treatment received in the forward areas was of the highest quality. Of the 82 cases, 70 or 85 per cent, had received wound débridement prior to admission. There were 10 patients, 12 per cent, who had not been débrided prior to admission. One of these had a primary type of wound excision performed after admission, but the others presented wounds which were not considered suitable for any procedure other than the providing of adequate drainage. In 2 cases it was uncertain from the data accompanying the patient and from the appearance of the wound whether débridement had been performed. Of the 70 cases in which débridement had been done, the time interval between injury and operation was accurately determined in 66. It is a tribute to the medical personnel in the forward areas that 51.77 per cent, of these were débrided within 12 hours and that only 15.23 per cent, had operations after that period. Of the entire group of 82 patients, it is known that 62 per cent were débrided within 12 hours of their injury.

The débridement, it is felt, was adequate in most cases. Improvement in the condition of the wounds was readily noted as the experience of the forward surgeons increased. In a few cases it was apparent that there had not been sufficient incision of the deep fascia and in some, injured muscle and foreign bodies were not removed, thus causing subsequent difficulties. Occasionally vaseline gauze had been inserted tightly in the wounds and acted as a cork instead of a drain. In such instances removal of the gauze was followed frequently by a gush of purulent material. Wide incision of skin to explore the depths of the wound, and counter incisions posteriorly on the medial or lateral side, were recognized as helpful measures in avoiding wound complications.

It is not known how many patients with this type of injury succumbed to shock or hemorrhage in the forward areas. However it soon became apparent that next to the treatment of shock and hemorrhage, the adequacy of the débridement was the most important part of the primary treatment both as to the saving of lives, the avoidance of soft tissue and bone infection, and the rapidity of convalescence.

Suture In only one instance had the wound been sutured before admission. The sutures were removed upon arrival at the hospital. Our experience with other cases in which battle wounds were sutured primarily has convinced us of the wisdom of the Surgeon General's Circular letter No. 189, dated November 17 1943 which forbids primary suture of such wounds. The gravest complications may ensue if immediate closure is performed. In none of our cases had any form of internal fixation of the fracture been attempted.

Immobilization The commonest type of immobilization used in the forward areas was the plaster spica. Most of these were double spicas, with plaster down to the toes on the affected side and to the knee on the opposite side. Of the entire series, 68 patients, 83 per cent, were so immobilized. Although many of the spica plasters were broken at the groin, the patients were for the most part comfortable, and this method of temporary fixation seemed entirely satisfactory. In 3 cases a Kirschner wire had been inserted through the femur and incorporated in the plaster but this seemed unnecessary. In our opinion the function of the forward stations, once excision and immobilization has been accomplished, is to evacuate the patient to a fixed installation for definitive treatment as soon as possible. If this can be done within a week, only ordinary precautions need be taken for the maintenance of length and for the proper alignment of fragments. The only thing that is required, after the care of the wound and the treatment of shock and hemorrhage, is comfortable transportation by a method which will prevent motion of the fragments. Adequate reduction can be obtained when the fixed installation has been reached.

It is inadvisable to cover with plaster any wound that has not been debrided, unless specific notation of this omission has been written plainly upon the plaster. It is also inadvisable to apply a nonpadded plaster when a patient's circulation cannot be continually and carefully watched. Padded plasters should always be used for transportation. If unpadded plasters have to be used because of lack of suitable material for padding the plaster must be split longitudinally through its entire length. The application of a nonpadded plaster especially in the region of the calf, proved to be an important factor in producing circulatory disturbances in several of our cases. Plaster fixation is a definite disadvantage in those instances in which wound infection is suspected. If infection is likely a window should immediately be made over the wound for early inspection

or the plaster should be removed entirely. It is probable, if earlier wound inspection had been made, that one of the deaths in this series could have been prevented.

In 12 cases, 15 per cent, immobilization was obtained by means of the Army half ring leg splint. This splint gave satisfactory temporary immobilization of the fragments but several points are worthy of mention. Any form of hitch used around the foot and ankle is dangerous because it may produce circulatory obstruction or pressure necrosis. Skin traction by means of broad adhesive strips or stockinette is the method of choice. Circular adhesive strips should not be used. Smoothly applied gauze bandage should be used to anchor the adhesive. Pressure from adhesive over the malleoli and over the head of the fibula should be avoided. The adhesive or stockinette should extend to a point just below the wound. When possible, a wooden spreader should be employed. If the lateral adhesive strip is applied somewhat more posteriorly than the medial one, there will be a tendency to correct the external rotation deformity.

The "Tobruk splint" was not used in any of our cases. In 3 of them, however, the wound and the adjacent arm of the Army leg splint were incorporated in a plaster cuff. It is felt that when there is a shortage of plaster in the forward areas, immobilization can be satisfactorily obtained by means of the Army leg splint, provided that such fixation is not maintained for more than a few days and that no ankle or instep hitches are used. The plaster spica, however, is preferable.

Two patients arrived without any form of immobilization. Both were in poor general condition and had severely infected wounds.

Sulfonamides and antisepsis. In 94 per cent of the patients there was either a written record of sulfanilamide having been used in the wounds or evidence of it on inspection. It is entirely possible that sulfonamides were applied locally to all wounds. In 40 per cent of the cases a history or written record of the oral use of sulfonamides was obtained. It is probable that a large number had taken the drug. Two sulfonamides, sulfadiazine and sulfathiazole were used and these in about an equal number of cases.

A stimulating dose of tetanus toxoid had been administered to all American soldiers prior to admission. Most of the Chinese had received 1500 units of tetanus antitoxin. Those who had not previously received it were given antitoxin at the hospital. No case of tetanus developed. Gas bacillus antitoxin was administered prophylactically in a few selected cases.

In summary, it is our opinion that the following factors are of greatest importance in the early management of these cases (a) treatment of shock and hemorrhage (b) thorough wound débridement (c) local and oral sulfonamide therapy (d) adequate immobilization and (e) rapid evacuation to a fixed installation. Fracture reduction and maintenance are of secondary importance. These are functions of the fixed medical installations.

CONDITION ON ADMISSION

General Although all the patients presented some degree of anemia and malnutrition and showed the effects of exposure only 18, or 22 per cent, were thought to be in poor general condition. This latter group consisted chiefly of patients with wound infection especially by gas-forming organisms, and patients with septic arthritis of the knee joint. The average hemoglobin determination in the entire group was 9.7 grams the white cell count averaged 10,000. There were, of course, wide variations, the hemoglobin being as low as 4.5 grams, white count reaching 26,000.

Wounds It was not always possible at the time of admission to determine which wounds were "infected." In our earlier cases there was a tendency to postpone inspection of the wound as long as possible in order to avoid contamination. It was later realized however that the usual criteria—fever, rapid pulse, leukocytosis, and general appearance—were not always reliable indications of infection, especially infection due to gas-forming organisms. As our experience increased we tended to inspect the wounds earlier and upon slight suspicion. On the other hand it is conceded that wounds which appear superficially infected on initial inspection may heal without complication if undisturbed. We feel that the error of omission is the more serious. The average period before wound inspection was 4 days in the entire series, but the large number of immediate or 24 hour inspections was offset by one case in which the wound was not examined for 8 weeks. It was felt that once we could assure ourselves of the appearance of the wound and the adequacy of the débridement subsequent dressings could be kept at a minimum.

There were 2 instances of massive gas gangrene and 3 of gas cellulitis. Otherwise there were no patients with spreading soft tissue infections, invasive cellulitis, or lymphangitis. A large number of wounds contained superficial necrotic material, and many showed evidence of surface infection. A few wounds had been plugged with vaseline gauze and spreading infection was un-

doubtedly prevented by prompt removal with release of dammed up blood and exudate. The first inspection of the wound revealed evidence of deep abscess formation in 4 instances. Secretions from the wounds were not routinely cultured.

In wounds which had penetrated the knee joint there was a high incidence of infection. Of 8 such cases, 4 developed joint infection and these were the sickest patients of the group and the most difficult to treat.

We believe that early inspection of thigh and knee wounds following admission to a fixed installation is a good general principle if the initial toilet of the wound has been carried out elsewhere. Gas infection can be discovered at the earliest possible moment a secondary débridement can be done if the primary operation was inadequate deep soft tissue infection can be controlled by early drainage and the form of subsequent treatment can be more readily determined. Afterward if the wound is satisfactory minimal frequency of dressing is advisable.

Metallic foreign bodies were noted in the wounds by roentgenologic examination in 33 patients 40 per cent many of them multiple.

Fractures It has been a common observation that in gunshot fractures of the long bones there occurs very marked comminution and fragmentation but it is generally noted that the classical bone displacements do not occur. This series of cases however was rather consistent in demonstrating the typical displacements of the fragments. In the upper third the proximal fragment was commonly flexed abducted and externally rotated. In fractures of the middle of the shaft, there was usually a slight amount of flexion of the proximal fragment. The lower third fractures almost invariably presented posterior displacement of the lower fragment due to the pull of the gastrocnemii. Approximately 80 per cent of the fractures in this series were in poor position upon admission to the hospital. Since they were received relatively early this fact played little part in the ultimate results.

Associated injuries Circulatory embarrassment is one of the gravest causes for concern in the management of these patients. It is significant to note that in 9 cases, 11 per cent, there was evidence of impaired circulation of the extremity. Most of these occurred in nonpadded plasters and when the plaster was split constriction was noted usually at the calf. Except for 2 cases of gas gangrene which resulted in death the circulation returned to normal following the splitting of the plaster through its entire length. We found hypesthesia and hypalgesia to be the usual early

wire through the lower femur. Anterior angulation usually occurs; this can be promptly corrected by placing the wire through the tibia. There was evidence of widening of the knee joint as a result of tibial traction in only 2 cases (Fig. 1). The wounds in both of these patients were severely infected with no hope being held for subsequent joint motion.

The most difficult deformity to correct in lower femoral fractures was persistent posterior angulation. This often could not be overcome by flexion of the knee or by manipulation. It was found that, with the wire through the tibial tubercle, the hinge of the Pierson attachment at the fracture site instead of at the knee, and with both the line of traction and the tibia maintained in the horizontal position, the posterior angulation was readily corrected (Fig. 2). This was the only type of case in which the line of traction was not made parallel with the shaft of the femur. It is important to maintain a firm support beneath the site of posterior angulation. A well padded Cramer wire splint placed on mullin slings and bent to the desired curve readily serves the purpose. The area must be carefully watched for signs of pressure irritation.

In fractures of the middle and upper thirds, the wire was inserted through the lower femur at the junction of the shaft and condyles and halfway between the anterior and posterior surfaces. We feel that control of the lower fragment is best obtained by the lowest insertion of the wire that can be accomplished without penetrating the knee joint. Placing the wire through the femur has the added advantage of permitting knee joint function at an earlier date. In fractures of the proximal third, marked flexion and abduction of the thigh are usually required; in addition, external rotation may be necessary. Middle third fractures require very little thigh flexion. In cases with knee joint infection, flexion of the knee was limited to 5 degrees in order to avoid persistent flexion deformities.

Satisfactory length and alignment were obtained by these methods in almost every patient admitted within 3 weeks of the original injury. Only an occasional manipulation of the fragments under anesthesia was required.

When the wire had been inserted through the femur passive knee motion was begun at the end of 8 weeks. A rope and pulley arrangement was fastened to the end of the Pierson knee piece, and the patient was able to control the motion of his knee within the limits of comfort. Tibial traction cases obviously did not have knee motion until the wire was removed.

Skeletal traction was continued until there was roentgenologic evidence of bone union. Union occurred on an average in about 12 weeks. The wire was then removed and the patient maintained in suspension for an additional 2 weeks, during which time knee and hip motions were encouraged. Most of the American patients were immobilized in plaster at this point and sent by plane to the Zone of the Interior. The Chinese patients were kept in bed for an additional month and received daily massage and active and passive motions of the extremity. Quadriceps exercises were stressed from the beginning of treatment. Guarded weight bearing was permitted only after 18 weeks, but it was impossible to control many of the Chinese patients, some of whom began to walk at the end of the 14 week suspension period. Several refractures were the result of early weight bearing and these delayed convalescence considerably. No leg braces were available at this time.

There were remarkably few complications resulting from the wire traction. There were no soft tissue or bone infections at the site of the wires. Only one wire snapped, and this occurred at the end of 12 weeks traction. Three tibial wires pulled out into the soft tissues and had to be replaced. This accident was caused by too superficial insertion of the wire into the tibial tubercle. In one case the traction bow became loose from one end of the wire, and the wire was pulled out through the other side by the weights. This occurred at the end of 8 weeks, and there were no ill effects, further traction being unnecessary.

Residual stiffness of the knee was a problem in many cases. It is impossible to determine which cases will develop this stiffness; length of immobilization is not the only factor. Personal variation in the willingness of the patients to co-operate, their ability to tolerate discomfort and their desire to get well, are qualities of major importance. Early active and passive motion of the knee is certainly to be encouraged. Physical therapy must be regular and intensive. Gradually increasing manipulation of the knee by the physical therapist with the patient prone and the fracture site supported, was useful and did not produce any untoward results.

Forceful manipulation of the knee under anesthesia however was disappointing. Tears of the quadriceps mechanism were produced in 2 cases, which further delayed the patient's convalescence. Even when improvement in knee motion was obtained, it was always fleeting since increased postoperative discomfort militated against the patient's maintaining the increased range of

Fig 1 Widening of the knee joint due to traction through the tibial tubercle in a supracondylar fracture with septic arthritis.¹

motion. In several cases the result was a poorer functioning joint than before the manipulation.

Wedge plasters were more productive of beneficial results. In cases with limited flexion a circular plaster was applied from ankle to groin and muslin hinges were incorporated in the plaster on either side of the knee. An elliptical window was removed from the plaster behind the knee and a transverse incision was made in it anteriorly. Each day the anterior opening was enlarged by blocks of wood and the range of flexion gradually increased. Care was taken to extend the knee completely each day before increasing the wedge in order to avoid the possibility of ending with a knee which had increased flexion but could no longer be extended. In the reverse situation when there was limitation of extension with consequent faulty weight bearing wedge plasters were also helpful; the window being placed anterior to the knee and the joint gradually extended.

COMPLICATIONS

Thrombophlebitis. The diagnosis of thrombophlebitis was made in only 2 instances. One of the deaths was shown at autopsy to be due to a pulmonary embolus secondary to a thrombo-

Fig 2 a Marked posterior angulation of fracture of distal third of femur. Persistent deformity on Braun Boehler splint. b Satisfactory alignment obtained by placing joint of Pierson leg attachment under the fracture and making traction in the line of the tibia.

phlebitis of the pelvic veins on the side opposite the femoral fracture and associated with an osteomyelitis of the ilium. The other instance was diagnosed after the patient became ambulatory when swelling of the leg was noted and palpation revealed definite evidence of a thrombosed femoral vein.

Secondary hemorrhage. Secondary hemorrhage was noted in 4 instances, 5 per cent. One occurred 3 days after injury. At operation a popliteal artery which had been severed in battle was found. Gas gangrene not recognized previously was also discovered at operation and necessitated amputation. The patient died within 12 hours probably from toxemia since blood loss was minimal. Two cases had wounds involving the femoral artery which bled 6 and 10 weeks respectively after injury. In both cases the artery was ligated and satisfactory collateral circulation was established. The last patient of this group did not bleed until 16 weeks following injury. At operation a false aneurysm of the femoral artery was found. This was repaired but subsequent amputation below the knee was required because of deficient circulation. It is interesting to note that in all 4 patients the ankle pulses were palpable on admission and that the circulation at that time seemed adequate. Secondary hemor-

Fig. 3. a, left, Comminuted fracture of middle third of femur with multiple metallic fragments. b, Same case at 3 weeks. Typical example of low grade localized osteomyelitis with sequestrum.

riage was always considered an absolute indication for immediate exploration of the wound.

Refraction. In 6 patients 7 per cent refraction occurred usually following some minor trauma. One developed while the patient was still in traction during an epileptic seizure. These patients were treated either by plaster fixation or reapplication of wire traction. Five of them obtained eventual bone union and the sixth was returned to the Zone of the Interior before this could be determined. Of the 6 refractions, 5 were in patients having definite bone infection. We feel that we erred in applying the same criteria for length of immobilization in the bone infection cases as in the clean cases. The former should have been given a longer period of fixation. The

Fig. 5. a, left, Early film of severely comminuted fracture with marked bone loss. b, Film taken 9 months later shows solid bone union.

use of leg braces might have prevented some refractions, but they were not then available.

Bone infection. Bone infection of some degree developed in 23 patients, 28 per cent. Unless associated with septic arthritis of the knee this was not a difficult problem. Bone union eventually occurred in all but one who had massive bone loss. His case is discussed later. Of the 22 remaining cases only 2 showed significant delay in bone healing as shown roentgenologically.

With one exception which was diagnosed by persistent drainage and the operative removal of a sequestrum these cases showed x ray evidence of localized osteomyelitis. The films did not reveal in any instance a spreading type of bone infection. In no case did a metastatic abscess develop. Figure 3 is a typical example of the minimal type of bone infection which was encountered. It is possible that the local and general use of the sulfonamides has modified the course of the bone infection as shown clinically and by films surely no very serious infection was observed.

The only operative procedure which was, we considered, indicated in these bone infections was incision and drainage, with or without sequestrectomy. Often this was done in the ward with the patient still in traction, usually under pentothal anesthesia. Posterior drainage by counter incision is very important, and the possibility of gravitational abscess must be kept in mind.

A draining sinus was the only persistent abnormality in this group. Sometimes it remained as

Fig. 4. Nonunion due to very marked loss of bone.

long as 10 months and it is certain that some of these patients will require further surgery.

We have analyzed the various factors which might conceivably influence the occurrence of infection. Among these factors are anemia, the presence of metallic foreign bodies, the interval which elapsed between injury and débridement, and coincident penetration of the knee joint. As almost all patients had débridement and sulfonamide therapy it was difficult to assess their value in the prevention of infection except by impression. When the other factors are tabulated it is found that, with two exceptions, there is no significant difference between the cases in which infection developed and those in which it did not. The average hemoglobin level on admission was 11 grams in the cases which remained free of infection and 7 grams in the infected cases. This emphasizes the importance of early replacement of blood loss by whole blood transfusions. Second, when the fracture communicated with the knee joint the likelihood of bone infection was increased threefold. It is our belief that the adequacy of the débridement is the most important single factor in the prevention of infection. It would appear from our data that the golden period for débridement has been extended by the use of the sulfonamides, since we found the incidence of infection in the patients débrided less than 12 hours almost identical with those débrided more than 12 hours.

Septicemia. In all cases with prolonged febrile course or severe toxicity blood cultures were taken, but in none was there evidence of septicemia. In none could the diagnosis be made on clinical grounds.

RESULTS

Mortality. There were 4 deaths in the group, an overall mortality of 4.9 per cent (Table I). Two were from diseases not directly related to the fractured femurs. One patient was found on admission to be suffering from a severe dysentery and died from peritonitis secondary to perforation of ulceration in the colon of unproved etiology. At autopsy no infection at the fracture site was found. The other died of pulmonary embolism following a sequestrectomy done for osteomyelitis of the pelvis on the side opposite the femoral fracture. The 2 remaining patients died of gas gangrene. Both of these had amputations which were performed too late. Earlier operations might have saved both lives. One arrived in a plaster spica 2 days after injury. The seriousness of the infection was not recognized until 24 hours later when a mild secondary hemorrhage demanded exploration of the wound. The other

arrived 7 days following a perforating bullet wound which had not been débrided. A transfusion given in preparation for operation resulted in a severe hemolytic reaction with chill, prolonged hypotension and subsequent jaundice, hemoglobinuria, and oliguria. The only chance for saving this patient was lost by waiting for recovery from this reaction rather than operating immediately. When operation was performed 4 days after admission, he was in such poor condition that the result was inevitable: blood transfusion should have been used as an adjunct to operation rather than preparation for it.

Amputations. Two of our 3 amputations were performed because of gas gangrene. The third followed repair of a false aneurysm of the femoral artery. The latter patient made an otherwise uneventful recovery.

Bone union. Of the 78 patients who lived there was one amputation, and 3 patients were transported to the Zone of the Interior before the end results could be determined. Of the 74 remaining cases, 71 or 96 per cent showed clinical and roentgenologic evidence of bone union. Two cases of nonunion had massive loss of bone (Fig. 4). In the other instance, a clean case, the cause was unexplained. While the great majority of fractures united in from 12 to 14 weeks, some were observed for 8 to 10 months before we were satisfied that union was secure. There was surprisingly satisfactory union in several cases with marked bone loss (Fig. 5).

Functional results. American patients were returned to the States too early to judge the

functional results. The Chinese however were kept in the hospital long enough for us to estimate with reasonable accuracy their degree of functional recovery. There were 3 deaths in this group and, of the 67 remaining patients, 45 or 67 per cent, had good functional results. In 16 or 24 per cent the result was only fair and in 6 or 9 per cent it was definitely poor.

The chief cause of unsatisfactory results was residual stiffness of the joints, especially the knee. There were 11 such cases. Shortening angulation and nonunion accounted for an additional 7 cases, and 4 patients had sciatic nerve injury.

SUMMARY OF IMPORTANT POINTS

An intensive study of 82 gunshot fractures of the femoral shaft incurred in action in the North Burma campaign of 1943-1944 revealed the following points worthy of emphasis:

1. The function of the forward surgical groups is the treatment of shock and hemorrhage, adequate débridement of wounds, institution of prophylactic chemotherapy, immobilization of fractures, and early evacuation. Definitive treatment of fractures should be reserved for the fixed installations.

2. In the prevention of infection the most important single factor in the early treatment of wounds is the adequacy of the débridement.

3. A spica plaster is a satisfactory method of temporary immobilization. Nonpadded plasters should not be used but if used by necessity, they should be split through their entire length before transportation.

4. No ankle or instep hitches should be used in connection with Army leg splints.

5. Early inspection of the wound at the fixed medical installation is advisable to rule out infection, especially by gas-forming organisms. Afterward dressings should be reduced to a minimum.

6. Incision and drainage should be instituted early when there are knee joint infections or deep subfascial abscesses. Dependent counter-incisions are necessary.

7. Circulatory impairment is serious and not uncommon. It must be recognized early and the cause eliminated.

8. Anemia, malnutrition, and the effects of exposure must be combatted. Early replacement of blood loss by whole blood transfusion improves the general condition of the patient and helps to prevent infection.

9. Balanced skeletal traction suspension is a very satisfactory method of treating these patients in a fixed installation.

10. When traction suspension is used, the possibility of gravitational abscesses should be watched for and early drainage should be accomplished.

11. Kirschner wires through the lower femur and upper tibia proved very satisfactory and there were no untoward effects. Each location has its advantages for certain types of fracture. The wires should be changed from one location to another when indicated.

12. Posterior angulation of lower femoral fractures can be corrected by placing the wire through the tibial tubercle and making traction in the line of the tibia instead of the femur.

13. Repeated roentgenologic examination is essential in treating these cases by traction suspension. Overpull must be avoided.

14. When there is associated knee joint infection, flexion of the patient's knee in the traction suspension apparatus should be limited to 5 degrees.

15. Traction should be continued until there is roentgenologic evidence of bone union. The average time for bone union was 12 weeks. Knee joint motion should be encouraged after 8 weeks.

16. Forceful manipulation of the knee is of no value and may do harm. Wedge plasters, however, are of considerable assistance in the relief of persistent joint stiffness.

17. Secondary hemorrhage from a wound, however slight is a positive indication for immediate exploration.

18. Refractures usually heal but convalescence is considerably prolonged thereby. Patients with precarious union should be kept in suspension for an added length of time. Afterward leg braces should be used when they are available.

19. Bone infection did not predispose to nonunion, nor did it significantly delay the time of bone union as seen on the roentgenograms. However, refracture in these cases must be avoided by a longer period of immobilization than in the clean cases.

20. The osteomyelitis seen in our cases was localized, minimal, and easily controlled. It is possible that it was limited by the use of sulfonamides.

21. Retained metallic foreign bodies did not appear to predispose to bone infection.

22. There was a mortality of 4.9 per cent. Bone infection of some degree was noted in 28 per cent. Bone union occurred in 96 per cent of the survivors. The known functional end-results of 67 followed cases were good in 67 per cent, fair in 24 per cent and poor in 9 per cent.

THE DIAGNOSIS OF ACUTE FLEXOR TENDON TENOSYNOVITIS

WILLIAM R. MOSES, M.D., Washington, D.C.

THE greatest difficulty in the care of infections of the hand is the diagnosis and differentiation of the types. This statement was made by Kanavel who also remarks concerning tenosynovitis, "This type of infection is much more difficult to recognize (than lymphangitis) and the surgeon is often in doubt as to whether he is dealing with a lymphangitis or a tenosynovitis. He might well have added or both."

Thus does one of the fathers of hand surgery express the uncertainty of exact diagnosis in many cases of these grave infections. However the correct treatment of tenosynovitis is surgically the exact opposite of that of simple lymphangitis and allied conditions of the hand therefore an exact diagnosis must nonetheless be made. If the indifferent results so often attending the care of these infections are to be improved, irreparable damage is the penalty for late or faulty diagnosis.

As outlined by Kanavel, the cardinal signs and symptoms of acute tenosynovitis are (1) exquisite tenderness over the course of the sheath limited to its distribution (2) the semiflexed attitude of the finger (3) exquisite pain on extension and (4) symmetrical swelling of the entire finger.

Several difficulties, however, may and do detract from the specificity of this syndrome. An analysis of these signs reveals that they are not pathognomonic either singly or in combination. This may be demonstrated clinically by experience or by logical scrutiny. The first sign of tenderness limited to the sheath is camouflaged by the frequent association of tenosynovitis with such additional lesions as dermatitis, cellulitis, lymphangitis, burn or other trauma or hematoma. Furthermore, there is an occasional case encountered in which only a part of the sheath is involved as mentioned by Cutler. Second the semiflexed attitude is that adopted by patients with any acute disease of the finger because this is the position of rest for the part. Third the pain on extension is as characteristic of cellulitis or lymphangitis as of tenosynovitis because either flexion or extension of the digit will result in a distinct distortion of the soft parts including pain.

From the Surgical Service of the Gallinger Municipal Hospital.

Fig. 1. Actual flexion of involved finger is prevented by the engagement of the nail of the finger in the thumb nail of the examiner. Attempted flexion produces pain along the palmar aspect of the finger in the presence of acute tendon sheath infection.

when these are tender. Finally, symmetrical swelling is found usually in simple lymphangitis.

There remains, however, a method of examination which is a more direct approach to the tendon sheath. This test may be practiced in the following manner as illustrated. The nail of the involved finger is engaged in the thumb nail of the examiner in such a manner that actual flexion (and thereby compression of the soft tissues) is not allowed. The patient is then asked to attempt flexion of the member. It will be seen in the accompanying photograph that the examiner's forefinger may be used to steady the dorsum of the finger. In the presence of acute tendon sheath infection, acute pain is experienced along the palmar aspect of the finger due to the bowstring like tensing of the tendon against its sheath. Pain is consistently absent in infections involving the soft parts alone.

The author has used this test of differentiation in 23 consecutive cases of acute tenosynovitis, simple and complicated by other lesions as above mentioned. It appears to be a specific test.

ALBERT D. BALLOU AN APPRECIATION

THE initial issue of SURGERY GYNECOLOGY AND OBSTETRICS was published on July 1, 1905 with 600 paid subscriptions registered and a leading article written by Nicholas Senn. The trials and tribulations of the initial issue of the Journal have been written by Dr. Franklin Martin. As the Journal increased in popularity and number of subscribers it became certain that a man with a knowledge of printing and bookmaking must be chosen as General Manager. Many young men applied for the position, Albert D. Ballou was chosen. This was in 1907.

Educated in Iowa, the son of a Methodist minister and trained for a career in journalism, Mr. Ballou has occupied the position of General Manager of the Surgical Publishing Company of Chicago for the past 38 years. His modesty, loyalty, business sagacity and ability to build an organization which has been welded together through the years by a spirit of friendliness, co-operation, and mutual

respect have played a large rôle in the success of the Journal. He and his associates have been completely responsible for the format of the Journal, its attractive appearance and the high standards of its advertising material. The wisdom of his judgment and the clearness of his vision are reflected in its pages.

To Mr. Ballou Dr. Martin gave the task of organizing the mechanics of the first Clinical Congress of Surgeons in 1910. With each succeeding Clinical Congress, even after it became a part of the activities of the American College of Surgeons in 1913, he has discharged his responsibilities with great credit to himself and to the College of Surgeons. His meticulous fulfillment of tasks given to him, regardless of their magnitude or their relation to his primary responsibility, has always enlisted the profound admiration of his colleagues. Few laymen have such an extensive friendship among the surgical profession as he has.

The Board of Regents of the American College of Surgeons and the Board of Directors of the Surgical Publishing Company, as the time approached for his retirement, desired to record their appreciation of his invaluable service and to congratulate themselves upon the fact that his judgment and advice will still be available to them. It is their hope that the esteem and regard in which they hold him and their deep appreciation of a task of great magnitude well done will give added pleasure to his enjoyment of the future.

Irvin Abell

STRICTURES OF THE COMMON DUCT

STRICTURES of the common duct have always been a great problem to surgeons because results of repair have been so poor and their causation is usually related to an operation on the bile tract. In a study of patients with stricture Cattell noted a relationship to operative trauma in about 80 per cent of cases and Walters in 90 per cent of cases. In a study made recently at Illinois Research Hospital such a relationship was present in 76 per cent of cases.¹

It is no doubt true that in many instances the damage may have been done by infection or an abscess and not by actual trauma. Nevertheless there are so many instances in which actual section or ligation of the duct can be proved that it behooves all surgeons working on the biliary tract to take extra precautions for safety of the ducts during operation upon the biliary system.

From the standpoint of treatment the lesions can be divided into four major groups (1) local stricture which can be resected with primary anastomosis (2) stricture of the terminal end only allowing transplantation of the proximal stump into the pylorus or duodenum (3) stricture of the proximal portion allowing preservation of the sphincter of Oddi and (4) destruction or stricture of the entire duct. Repair of the first two types is comparatively simple and results will be good if certain pitfalls are avoided. For example in group 1 it is desirable to do the anastomosis over a rubber or vitallium tube but if a T tube is used it must not be brought out through the repair line but through an incision in the duct distal to it. In group 2 reformation of a stricture will be prevented to a great extent if

the mucosa of the common duct is anastomosed directly to the mucosa of the intestine (Cattell). In groups 3 and 4 the vitallium tube as introduced by Pearse can be used to advantage. Search should always be made for the distal end of the common duct since the sphincter of Oddi is such a valuable factor in prevention of regurgitation of intestinal contents into the bile ducts. It is difficult to explain the mechanism of production of the stricture in group 4 and particularly the high frequency of this type. We have been unfortunate in finding an unusually large incidence of this type at Illinois Research Hospital, encountering this type in over half of 24 cases of inflammatory or traumatic stricture. If search is thorough one can usually find the terminal duct or its remnant. We have not found incision into the duodenum for visualization of the sphincter of Oddi to be of much value to us. In almost all of our cases in group 4 we have found either a duct too small for function or one entirely obliterated. In view of multiple observation on a few cases, we are convinced that this obliteration can be gradual and can be produced by infection and disuse.

Because of the frequency and difficulty in repair of group 4 we have devoted most of our attention to this group. We have tried anastomosis to the duodenum or pylorus of the stump of the duct at the hilus of the liver with so many failures that we have abandoned it. All patients repaired after this fashion do well for 6 months to 2 years, but ultimately all except one or two of ours have returned with serious symptoms of recurrence of the stricture.

For this reason we began the use of a vitallium tube to bridge the defect but did not think it would be feasible to transplant the tube into a loop of intestine which was functioning theoretically the food stream would

¹Cole, W. H., Treason, Carl, and Reynolds, John. *Ann. Surg.* (in press).

dislodge the tube. We accordingly adopted the principle of anchoring the tube to the stump of the duct at the hilus of the liver with a pursestring suture, and inserting the tube into a defunctionalized loop of jejunum. In 5 cases we inserted the tube into a loop of jejunum, the arms of which were anastomosed hoping to shunt the food away from the tube thus minimizing possibility of regurgitation of food and intestinal contents into the intrahepatic ducts. To our surprise in the 4 patients who survived this operation, the food stream continued to flow through the arm of jejunum. All 4 patients developed cholangitis with chills and fever which was fatal to one. Two of the three remaining had the proximal arm of jejunum severed and valves made in the distal arm. These two patients have had complete freedom from chills and fever, indicating that regurgitation of food was the primary cause of cholangitis.

Having had poor results with the use of a loop of jejunum we later adopted the use of a defunctionalized arm of jejunum utilizing the Roux principle. We have operated on 7 patients after this technique. This method is similar to one recently reported by Allen except that he used a rubber catheter instead of a vitallium tube and made no valves to prevent regurgitation. All 7 patients survived this operation but one died 2 years after operation with Banti's disease, which we assume to be entirely coincidental. All 6 patients surviving have had excellent results 2 or 3 of them having had one or two mild chills early in their convalescence.

We obtained such definite evidence of the rôle of regurgitation of food into the intrahepatic ducts in the development of cholangitis that we have arrived at the conclusion that 2 or 3 valves created by infolding of the intestinal wall (or equivalent method) should be placed in the arm of jejunum to prevent

regurgitation and that at least 18 inches of jejunum should intervene between the anastomosis at the hilus of the liver and the end to side anastomosis of the jejunum.

On two occasions x ray observation at intervals has revealed passage of the vitallium tube after a few months. However, both of these patients have remained entirely well. In these cases at least the value of the tube could have been nothing more than temporary. Nevertheless we are convinced that a temporary support of some type is absolutely essential for a few weeks, to maintain an opening and prevent shrinkage or possibly a true stricture at the junction of the hilus and arm of jejunum. It appears logical to assume that if the opening was small or stricture formation developed the tube could not pass on account of the flange and funnel shaped tip. On the other hand after the sutures had cut through (which we assume would happen in a few weeks with release of the tube) the tube might be passed if the opening was large enough to allow passage of the flange and funnel shaped end. If the opening is this large after the process of healing and scarring has been complete the chance of stricture formation would appear minimal indeed. For this reason we believe that if the tube remains in place for 3 months it makes no difference whether it remains or passes, since the opening would appear sufficiently large to avoid stricture formation if large enough to allow passage of the tube after that interval. WARREN H. COLE

INTRAVENOUS AMINO ACIDS, PROTEIN DIGESTS—ACCURACY OF TERMINOLOGY

THE intravenous injection of nitrogenous substances for nutritional purposes has received widespread attention in the past several years. It is to the credit of surgeons that as a group they have

played a prominent rôle in the development of this field which is more closely related to the fundamental sciences than to clinical surgery.

In the literature concerning the practical application of intravenous nutrition with nitrogenous materials the terms "amino acids" and "casein" or "protein digests" seem to have been employed interchangeably. This is confusing especially to the chemists. A solution of amino acids is just that and is prepared by addition of these acids each in crystalline form obtained synthetically or by extraction. A protein may be decomposed to its constituent amino acids but the writer is unaware of a digest generally available at this time in which this has been accomplished. The several types of available digests represent mixtures of simple peptides and amino acids. It has not yet been demonstrated that utilization of intravenously administered digests and solu-

tions containing only amino acids are identical phenomena. Indeed it has not yet been determined which type of preparation is the most desirable.

Now that the general principles have been established, it falls to the chemists further to improve nitrogenous nutriment for intravenous use. In doing this they must take cognizance of clinical research with the several types of solutions employed. In the interests of accuracy and to facilitate a general agreement in the manner of recording experiences, the consistent use of "casein," "fibrin," and similar terms, "digest" should be employed where such solutions have been used. The term "amino acid solutions" should be reserved for solutions composed of these acids only. The terms mentioned should not be employed indiscriminately as they refer to different preparations. ALEXANDER BRUNSCHWIG

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE third edition of *Titus Management of Obstetric Difficulties*¹ like the first two editions is not intended as a conventional textbook. However it has been made more complete particular ly as regards an extensive bibliography. The emphasis on the practical nevertheless has been maintained and its aim as a working aid in dealing with obstetric emergencies preserved. Additions and changes have been made so as to bring this third edition grossly up to date. For example the Rh factor and erythroblastosis are thoroughly discussed, caudal analgesia is included in the chapter on anesthesia, the tech niques of extraperitoneal cesarean section are nicely described and illustrated and penicillin therapy is completely discussed in practical detail.

Because it covers mainly the abnormal phases of obstetrics, minimizing historical and therapeutic considerations and because it presents in a straight forward manner the practical aspects in the treat ment of these abnormal phases it should be avail able to all who may be faced with obstetric difficulties in practice or in training. It is of unlimited value to the general practitioner and to the obstetric house officer or resident. During my own hospital training the previous editions of this text were of the greatest aid, particularly in emergencies where a quick reference was needed. The author has expressly in tended this book to serve just such a purpose, consequently, he has avoided lengthy discussions of all the possible forms of therapy in any given situa tion, and has frankly expressed his own preferences which are based upon years of clinical experience and which are nearly universally acceptable. This book is a must.

STUART ABEL.

THE fourth edition of *Essentials of Body Mechan ics in Health and Disease*² by Goldthwait Brown Swaim, and Kuhns has decreased in size but has become more compact and concise while still retain ing its clarity. The book is more timely now than ever since there is so much stress on physical fitness nationally. The great number of rejections that oc curred in Selective Service showed the necessity for more stress on physical fitness throughout the country. The need for rehabilitation of the return ing service men, as well as the great problem of cor recting so many of the deformities and disabilities seen in civilians make this book of importance in

this connection also. Many of the deformities in adult life could be prevented by establishing good body mechanics in childhood.

The advantage to the individual with chronic illnesses in the correction of body mechanics is demonstrated in several chapters of the book. In this connection the work of Kerr showing the rela tionship of the heart and circulation to body me chanics is particularly interesting. The importance of keeping the aged in good physical condition which will improve their general well being is greater since the life expectancy has been definitely increased.

The chapter on the foot has been rewritten. The most common static deformity pes valgoplanus is conceived of as being a congenital defect in many instances, with the second toe longer than the first and the mechanism at the great toe more pliable than normal. The treatment described is by means of a series of exercises for the foot, in sitting and stand ing positions. To protect the weak foot, arch sup ports are recommended.

EMIL D. W. HAUSER.

A timely contribution to an important branch of surgery especially under war time conditions is Armstrong's *Bone Grafting, in the Treatment of Fractures*³.

The author a meticulous worker has excellent qualifications from the viewpoints of training as signment, experience and associations.

The value of bone-grafting in the treatment of fractures is well known. In the practice of this particular branch of orthopedic surgery one in evitably is confronted by many problems and prac tical difficulties. This book has arisen out of the difficulties the author has encountered.

In the foreword Mr. Watson Jones states that the principles of bone grafting were familiar to John Hunter two hundred years ago. He further states:

In his monograph of bone-grafting in the treat ment of fractures Mr. Armstrong's work reflects the surgical development of two hundred years—the research of Hunter, the work of Lister the in spiration of MacEwen, the skill of Lane and the craftsmanship of Albee. On this very sure foundation linked to recent research in metallurgy is based a technique of bone-grafting which almost completely solves the problem of slow union, delayed union and non-union. Mr. Armstrong has dealt faithfully with every detail of technique that the surgeon must know. As a leading member of the team of ortho-

¹BONE GRAFTING IN THE TREATMENT OF FRACTURES. By J. R. ARMSTRONG, M.D., M.Ch., F.R.C.S. Baltimore: The Williams & Wilkins Co., 1935.

²MANAGEMENT OF OBSTETRIC DIFFICULTIES. By Paul THOM, M.D. of St. Louis. The C. V. Mosby Co., 1945.
³ESSENTIALS OF BODY MECHANICS IN HEALTH AND DISEASE. By Goldthwait BROWN SWAIM, M.D., F.A.C.S., and Lloyd T. BROWN, M.D., F.A.C.S. Loring T. Swaim, M.D. John G. Kuhns, M.D., F.A.C.S. Philadelphia: J. B. Lippincott Co., 1945.

pedic surgeons of which the Royal Air Force is proud surgeons who have shouldered heavy responsibility, he with them has gained vast experience and treated the fractures of pilots and aircrews which are characterized by remarkable severity and multiplicity. In all their work the highest possible standard has been set, and it has been maintained by the vigilance of Osmond Clarke, a service consultant. But it has been achieved without standardization or suppression of initiative.

The technique of onlay bone-grafting with vital Hum screw fixation is well established. Brilliant results can be achieved—deformity can be prevented, union can be accelerated, nonunion can be avoided. But, let it be remembered that John Hunter was defeated by sepsis. Let it be remembered that internal fixation was no more than part of the contribution made by Arbuthnot Lane; no-touch technique was the other part. Even today the general standard of asepsis in operative technique is far too low. To infect a closed fracture is a disaster of the first magnitude; it is no less worthy of a court of inquiry than a railway disaster. The surgeon who proposes to adopt the recommendations of Armstrong's monograph must first achieve so perfect a command of aseptic technique that if, within a few days of operation, the patient develops a febrile reaction he can say with complete confidence: "He may have pleurisy, he may have pneumonia, but whatever he has, I am quite certain that he has no infection in the wound."

Armstrong believes that the onlay graft technique is the simplest and most efficient. The most effective available grafts are those cut from a normal tibia. The use of metal screws is the most reliable method of securing internal fixation.

He outlines certain basic considerations such as close and stable contact between large areas of raw bone on the graft and host; mechanically stable fixation of the graft and fracture; before grafting, the clearing of the fractured surfaces of fibrous tissue and sclerotic tissue; restoration of normal apposition and alignment of the fragments of the host bone. The architecture of the reconstructed bone as a whole should as far as possible at the conclusion of operation approximate normal.

Subjects discussed are the principles, general indications, contraindications, types, sources and fixation of grafts; preoperative and postoperative treatment; operative technique; cutting and preparation of grafts; fractures of the spine, clavicle, humerus, radius, ulna, carpal scaphoid, metacarpals and phalanges, neck of the femur, shaft of the femur, tibia, fibula, ankle, tarsus and metatarsals.

Arthrodesis has been discussed in connection with certain fractures of the tarsus and spine in which he believes it to be the best initial treatment.

Most of the roentgenograms and the statistics included in the Appendix were taken from the records of the Royal Air Force orthopedic centers. The author acknowledges the debt which he in common with all the other orthopedic surgeons in

the Royal Air Force owe to Mr. Watson-Jones and to Air Commodore Osmond Clarke. He pays tribute to every member of the orthopedic "team" in the center to which he is attached.

Those who will receive the greatest benefit from this book are the surgeons who have (1) the qualifications to do this type of work, (2) the interest, (3) the opportunity, and (4) adequate facilities to do it well, including physical set up, medical, surgical and allied personnel and equipment.

Minor criticism includes the thought that the double onlay graft has not been given sufficient space and illustration. Some of the colored illustrations are too highly colored. Some photographs are only fair-line drawings would have been more instructive. However, in spite of these criticisms, the book can be recommended without reservation.

PHILIP LEWIS.

A CONCISE presentation is made in *Hypertension and Hypertensive Disease* of the authors' concepts of hypertension and hypertensive disease with a critical analysis, almost approaching dogmatism, of many existing ideas on the genesis and management of these disorders. The material is well presented with considerable space devoted to functional evaluation and its bearing on the rationale of certain forms of therapy.

In the early chapters hypertension is defined and hypertensive disease is discussed. The authors consider essential hypertension as an indefinable physiologic disturbance (or disturbances) characteristic of this disease which ultimately leads to elevation of diastolic and systolic blood pressures, anatomical changes in the vascular tree, and functional impairment of the involved tissues. They feel that in the past physicians have been too interested in the level of the blood pressure and have neglected the primary cause. After considering the factors capable of altering blood pressure, they conclude that the responsible agent is a generalized vasoconstriction sufficient to increase the total effective peripheral resistance. The authors tend to show that although a humoral mechanism with a superimposed neurogenic factor is generally believed to cause vasoconstriction, controversial data exist which prevent this concept from being a reality.

This section is followed by a critical analysis of the renal mechanism in the genesis of human hypertension. They oppose the inference that experimental (induced) and human (spontaneous) hypertension are the same. Their conclusions are based on a detailed analysis of the cases in the literature in which bilateral and unilateral intrinsic renal disease in humans was considered the primary mechanism. By their own strict criteria a rare instance was allowed but the majority of cases were not accepted. Renal ischemia was also eliminated as the cause for hypertension in pregnancy.

HYPERTENSION AND HYPERTENSIVE DISEASE. By William Goldring, M.D. and Herbert Chown, M.D. New York: The Commonwealth Fund, 1944.

The chapter on the evaluation of the current medical and surgical treatment is too critical as the authors' criteria for evidence of cure is rigid and almost impossible so long as the cause of hypertension remains unknown. Anything which merely depresses the blood pressure is considered artificial when no attempt is made to combat the cause. Thiocyanate therapy was not recommended as it proved dangerous in their hands. They admitted that pyrogenic substances lowered the blood pressure but this was offset by the undesirable effects upon cardiovascular dynamics. Renal extracts were considered empirical, inasmuch as the authors believed that the fall in pressure resulting from their administration was probably associated with a pyrogenic reaction. Nephrectomy was definitely condemned. The newer concepts of amine-oxidase treatment were described.

The reader however is given some ideas as to treatment for a regimen is suggested which is conservative and logical. The management of hypertensive complications especially in pregnancy are worthy of comment.

Appendices are included at the end of the book which describe the technique of determining direct blood pressure measurements, cardiac output, and the various procedures used for determining renal function.

TERENCE R. VAN DELLEN.

THE author of the volume, *Radiologic Examination of the Small Intestine*, because of his scientific interest and tremendous experience, is one of the few qualified to deal with this important subject. Much of the material has been presented at instructional courses at the meetings of the American Roentgen Ray Society and the Radiological Society of North America. Those of us who have had an opportunity to attend these courses are indeed grateful that the author provided the profession with this fundamental material in the form of a book for study reference and reflection.

It has only been in comparatively recent years that any time or consideration has been given to the small intestine during a gastrointestinal examination. In most books published on the subject of the gastrointestinal tract little space is devoted to the small bowel. The author has had a wide experience in this field and has made every effort to correlate the roentgen with clinical, operative and postmortem observations. A thorough knowledge of the anatomy and physiology is paramount if one is properly to evaluate the roentgen findings and to differentiate the normal from the abnormal.

The author in his usual clear, concise, easily readable, and scientific manner devotes the first chapter to indications for roentgen examination technique, and the report of the small intestine study followed by a thorough description of the embryology, anatomy and physiology of the small bowel. He then describes the appearance of the normal small bowel

in the adult and the infant. Subsequent chapters are devoted to organic lesions such as intestinal obstruction the use of the Miller Abbott tube in the diagnosis and treatment of ileus disorders of nutrition, diseases of the mesentery, allergy, inflammations, neoplasms, anomalies, the effect of food and certain drugs on the small intestine and miscellaneous conditions. All of these conditions are discussed thoroughly with due credit given to the work of other investigators. The subject matter is well illustrated with excellent reproductions in the negative phase. An extensive bibliography is a further testimonial to the author's scientific approach to the subject.

This volume written by a man well qualified and completely familiar with the subject represents a truly outstanding contribution to the literature in the field of roentgenology. It should be in the library of every roentgenologist and any physician interested in the diagnosis of lesions of the intestinal tract. The publishers are to be congratulated on the excellence of the paper, the printing and the illustrations. It is recommended without reservation.

EARL E. BARTH

THE second edition of *Clinical Roentgenology of the Digestive Tract* by Maurice Feldman, which presents a clinical roentgenological consideration of diseases of the gastrointestinal tract has been thoroughly revised and completely reset. The importance of the diagnostic value of the roentgen examination is stressed throughout. The subject is handled in a lucid, concise manner well illustrated with excellent reproductions of roentgenograms and artists' drawings.

Separate chapters are devoted to the esophagus, stomach, duodenum, small intestine, colon, hernia, diaphragm, appendix, gall bladder, biliary ducts, liver, pancreas, peritoneum, omentum, mesentery and retroperitoneal tumors, lymphomatous diseases, abdominal vessels, spleen, the deficiency diseases and miscellaneous conditions. A systematic co-ordination and correlation of the clinical and roentgenological findings is emphasized in the discussion of every condition. The more recently described developments and methods of x-ray examination have been added. A complete bibliography is provided at the end of each chapter.

The author is to be congratulated for assembling such a vast amount of material into a single volume thus providing a source of accurate information on this important subject. The reviewer has found the first edition published in 1938 to be one of the most useful books in his library as an atlas for the medical students and as a helpful reference work providing a valuable and ready source of accurate information. The second edition is recommended without reservation to roentgenologists, gastroenterologists, students and general practitioners. The book should be added to the library of any physician

Interested in the accurate diagnosis of lesions of the gastrointestinal tract
Earl E. Burne

In simple, concise words the author's forty years of experience and teaching in the field of traumatic surgery is skillfully described in *Clinical Traumatic Surgery*. The valuable material in Dr. Moorhead's earlier books—*Traumatic Surgery* in 1917 and *Traumatic Therapy* in 1931—has been included and brought up-to-date by the excellent appraisal and discussion of improvements in the treatment of the injured. Chemotherapy and penicillin, early mobilization, Roger Ankerston reduction apparatus and Stader splints as well as many other advances are considered. This work is unusually well illustrated by photograph, diagrammatic sketches, many describing stages of treatment procedures such as reduction of the dislocated hip or the dislocated shoulder. The reproductions of x-ray films are not only excellently chosen but the reader can actually see the path logical condition described.

The 32 chapters covering 725 pages with 500 illustrations divide the field of traumatic surgery into logical categories in which the reader can quickly learn exactly where to find any particular type of traumatic problem discussed. The chapters on traumatic neurones, medicolegal phases of trauma, compensation problem and malpractice suits reveal the author's knowledge of the importance of these subjects in all traumatic surgery treatment. The chapter on war injuries is a fine abbreviated résumé of treatment of war injuries including much of the author's experience at the Pearl Harbor attack December 7, 1941 where he just happened to be at that time. One would expect Dr. John J. Moorhead to dedicate this book to "The Wounded at Pearl Harbor—In recognition of their courage and stamina and in tribute to their surgeon-comrades."

This book offers an excellent opportunity for the physician on duty in hospital receiving and examining room to study this field and should be there for ready reference. It should also be in every industrial medical department and dispensary for treatment of the injured. Since the general practitioner may occasionally or frequently be called upon to treat cases of injury, the volume offers an excellent ready source of reliable information.

One gains the impression of overcrowding of the pages necessitated by publication of this book under war time restrictions. Future editions that are certain to flow quickly I am sure will correct this condition where for example a new chapter follows the preceding chapter within an inch or two of the bottom of the page.

EDWARD C. HOLMES

Illustrations two in color, considerably broader in its scope than the title suggests. It is excellently written for the enlightenment of neurosurgical internes and young residents. From this standpoint it fulfills its mission well. The older neurosurgeons will find much of interest whether or not they agree on minor details as the book reflects the mature opinion of one of the pioneers in this comparatively new specialty. However the chief function of this work is the instruction of the novice. It is filled with simple truths, common sense observations and what to the experienced neurosurgeon may seem trivial or self-evident facts but which to the young man without such a background are valuable directives.

These are the simple instructions presented, knowledge of which we usually take for granted and cannot understand why the inexperienced fail to make the necessary observations and carry out the indicated procedures. Sachs anticipates the many simple complications which may arise before, during, or after a neurosurgical operation and gives detailed instructions to prevent or relieve them.

The book is written in almost a conversational manner which in some places leads to verbosity. The reviewer at times felt the desire to condense or eliminate sentences—to get more rapidly to the essential facts.

The first chapter deals with the preoperative examination and care of most neurosurgical conditions. Included is an outline of a very complete neurological examination and the special tests to be made in the diagnosis of certain intracranial tumors. Under separate headings which are carefully indexed are suggestions for the examination and early care of patients with head injury, brain tumor, brain abscess, neuralgia, hydrocephalus, spinal injury, spinal tumor, ruptured intervertebral disc, spina lida and peripheral nerve injury.

Subsequent chapters deal with the operating room preparation of the patient and general operative procedures. Included is a discussion of anesthesia, neurosurgical practices in the control of hemorrhage, the use of suction, cotton, and bone wax. The indications for and technique of vertebrolography are given.

Two chapters are devoted to operative procedures usually with detailed illustrative cases in which such operations were performed. Sachs presents his personal views gleaned from a wealth of material and years of practice as to the best procedure for a wide variety of neurosurgical conditions. Perusal of these by the inexperienced interne or resident, especially just before a listing in the operating room, would greatly enhance his value since he would know in general what was being done and could anticipate some of the needs of his chief. All the usual neurological surgery operations are well illustrated.

An excellent chapter deals with postoperative care a subject so often delegated to comorbid, inexperienced men. Included is the care of the

THE book *The Care of the Neurological Patient* by Ernest Sachs, containing 265 pages with 17

Illustrations. Published by J. B. Lippincott Co., Philadelphia, Pa. Price \$5.00. The book is available in paperback for \$2.50. The book is available in hardcover for \$5.00. The book is available in hardcover for \$5.00. The book is available in hardcover for \$5.00.

bowels and bladder postoperative fever the recognition of a postoperative clot frequency of dressings, and other simple, but from the patient's standpoint, important details.

A careful study of this work by the young resident staff will remove a considerable load from the neurosurgeon and will undoubtedly expedite the recovery of many patients.

MAX M. PERRY

THE breast may well be considered the organ of romance for more reasons than one. It responds to many influences: sexual maturity with its accompanying hereditary or basic variances; the menstrual cycles; pregnancies either going to term or interrupted; lactation brief or prolonged; intercurrent infections; pelvic disease affecting ovarian secretion, early or late in life, the menopause and subsequent senile involutional changes. The anatomical changes in the breast due to the above influences are so varied that, in truth, it is difficult to determine accurately what is within the normal and what is abnormal when one considers evolutionary changes which might present themselves in the largest number of relatively healthy individuals. The breast is an external organ therefore susceptible to fairly accurate evaluation of gross anatomical changes and with slight inconvenience material can be procured for microscopic examination. The examination of the breast is a real art that must be developed in the light of gross and microscopic studies that are properly interpreted. An answer to many of these perplexing problems may be found in the new second edition of *Diseases of the Breast* by Geschickter.

This second edition, follows the first which appeared a few years ago and which was considered by many to mark a milestone in monographic medical literature. New material has been added in this second edition chief of which is the criteria of operability and inoperability of mammary carcinomas; the relative merits of surgery and irradiation in cancer; the endocrine therapy of chronic cystic mastitis; and the etiology of mammary carcinoma. This new edition of approximately 800 pages contains 593 illustrations and many tables.

It is impossible to review adequately this work because of the tremendous amount of material it contains. The basis for opinions and conclusions by the author is placed upon a study of clinical cases seen in the wards of the Johns Hopkins Hospital, a critical analysis of case histories, specimens, and follow-up studies recorded in the Surgical Pathology Laboratory of the Johns Hopkins Hospital and experimental evidence obtained by the author in his own investigative work and that of others. Included is a description of the normal development and functional changes in the mammary gland, the endocrine physiology of the breast and the breast in pregnancy and lactation. The author seems to have

simplified somewhat the subject of chronic cystic mastitis considering it as a mammary dysplasia of varying types. The endocrine aspects of this condition are discussed and, what is important, the possible rôle of mammary dysplasia may play in the occurrence of cancer. It would appear that this latter is the prime factor since by far the largest percentage of breast lesions which are benign do not endanger the life of the patient nor do they markedly handicap the individual. It is the fear of the presence of cancer or the possibility that the lesion is the forerunner of cancer that distresses the patient. In consideration of this association between chronic cystic mastitis and carcinoma, the author states in the preface of this second edition: "The incidence of carcinoma in chronic cystic mastitis (less than three per cent) has been supported by additional statistics and the importance of endocrine factors in the etiology of benign and malignant mammary neoplasms has been extensively confirmed."

Many pertinent facts are presented in the discussion of benign mammary tumors in the light of estrogenic stimulation. In 328 pages devoted to a complete consideration of cancer of the breast reference is made again to the importance of recognizing a thorough radical mastectomy as the treatment of carcinoma of the breast in the so-called operable stage. One point the author brings forth is difficult to comprehend. In advising irradiation after radical mastectomy when axillary nodes are present, he states that there is about 5 to 7 per cent increase in the 5 year survival over that procured with only the radical mastectomy. It would seem logical to conclude that by far the largest percentage of deaths due to carcinoma of the breast are the result of distant metastases such as to the viscera and not to purely local recurrences. The question involved is whether such fatal visceral metastases are the result of local recurrences or whether they were present or took place at the time of the radical mastectomy. If the former then postoperative irradiation might be of benefit but if the metastases were present at the time of operation irradiation will be of no final benefit. Serious consideration must be given to events that may occur when the patient is examined while the diagnosis is made such as excessive manipulation of the breast, thus spreading the disease and possible spread during the operation.

The experimental evidence on production of mammary dysplasias and tumors including carcinoma is extremely interesting. One cannot escape the conviction that the promiscuous administration of hormones especially the estrogen group may have potential dangers. This warning may be timely now when there seems to be a trend to give women estrogenic substances for so many resistant conditions and complaints that do not yield to commonplace therapy.

The author has without doubt accomplished his purpose which is well expressed in the preface to the first edition: "In recent years contributions to the

DISEASES OF THE BREAST. By Charles F. Geschickter, M. A., M. D. With special section on treatment in collaboration with Murray M. Campbell, A. B., M. D., F.A.C.S., 2d ed. Philadelphia, London: Mosby, J. B. Lippincott Co., 1945.

etiology the diagnosis and the treatment of mammary disease have accumulated rapidly. Much of the progress made can be attributed to the different groups of special is interested in these problems. The specialties concerned include surgery, radiology, obstetrics and gynecology, pathology, endocrinology and laboratory technology. In bringing together in this volume the work done in these diverse fields the usefulness of this information to the general practi-

tioner as well as to the specialties enumerated has been the foremost in mind." In this volume there is placed at the disposal of the practitioner an enormous amount of information that he must have if he expects fully to comprehend his responsibilities and escape the pitfalls before him when diagnosing and treating diseases of the breast. The many excellent illustrations add much to the text.

I proposed prophylactic treatment consists of education of the laity and the profession to lead to early diagnosis and conservative treatment. Cleanliness should be advocated and prevention of undue chronic skin irritation especially prevention of carcinogenic exposure in industry under the supervision of industrial surgeons.

The differential diagnosis includes syphilis (especially tertiary lesions) mycosis fungoides leprosy leishmaniasis, skin tuberculosis, Bloch's sarcoid lupus erythematosus, and lupus verrucosus.

Treatment consisted of a routine in which 90 per cent of the cases were referred to surgery and 10 per cent for radiation alone. Biopsy of large but not obvious carcinomas was practiced small lesions were excised for biopsy. In the author's clinic excision gave prompt and often superior results as compared to radiation especially when the late effects of radiation skin atrophy and telangiectasias are considered. He did not believe that radiation therapy was successful despite some excellent late results in the cases in which bone or cartilage were involved. Painful cases when inoperable or when the patient had an uncontrolled systemic disease or was of an extreme old age with cardiovascular disease, were referred for radiation. Less extensive carcinomas involving only the soft tissue were also referred for radiation.

Surgical high-frequency currents were used for desiccation until all the lesion was removed when the lesion did not exceed 5 mm. Inexperienced use of the high frequency current often resulted in deep and indolent ulcerations. Radium after electro-desiccation is not thought necessary.

Adequate surgical resection wide of the tumor is the treatment of choice. Special problems exist in the case of lesions of the nasolabial fold in which involvement of the nasal cartilages or ethmoid or maxillary sinuses is frequent, and in the case of lesions of the ear in which early metastases to the regional lymph nodes are seen. Results in such lesions are not always favorable except in very small early lesions unless radical procedures are followed. In the more advanced or recurrent lesions extremely wide excision and electrocoagulation is preferable and it is often successful after simple surgery or radiation has failed. Novocaine block and local infiltration is the preferred type of anesthesia no spreading of the tumor by the needle was observed.

When possible, immediate reconstructive procedures were done, even in radical resections. In the cases of bone or cartilage extension monthly biopsies of suspicious areas, followed by further excision if positive, were practiced for from six months to a year before plastic operations were done. Tiersch-Ollier skin grafts and pinch grafts for infected defects, and skin flaps and full thickness grafts for larger defects were used. A complete statistical analysis of the surgical and radiation therapy is given. The results seem to be excellent.

A method of regular follow up to catch early new cases or recurrences for a period of from three to five years, or preferably for a lifetime at yearly intervals after five years is practiced.

JAY P. BARTLETT, M.D.

EYE

GILMAN, R. U.: An Analysis of 100 Cases of Strabismus Treated Orthoptically. *Brit J Ophth.*, 1945 29 450.

This article is a study of binocular function in 100 patients who were treated in 1943 and 1944 at the West Bromwich and District Hospital. The patients were divided into 3 groups.

1. A group of 63 who were treated by orthoptic methods only. The results showed that in 36 patients the condition was corrected and there was good stereoscopic vision.

2. A group of 37 patients who were treated by both orthoptic methods and surgery. In 23 the eyes were described as straight and 17 of these developed good or fair stereoscopic vision.

3. A controlled series of 50 patients under observation for an average of nine months with no treatment other than lenses. This treatment did not result in the development of stereopsis in any case.

An analysis is made of the refractive findings in the 100 patients studied. The question of a possible strabismus is discussed, and the absence or failure of stereoscopic vision is held to be the greatest etiological factor in its development.

HUGHES H. RICHARDS, M.D.

Shenkin, H. A., and Leopold, I. H.: Localizing Value of Temporal Crescent Defects in the Visual Fields. *Arch. Neur. Psychol.*, Chic., 1945 54 67.

The fact that the most peripheral portion of the temporal visual field has an unpaired representation in the optic pathways and visual cortex has been well recognized. This unpaired portion is called the temporal crescent or half moon. The paired portion has a diameter of approximately 120 degrees and the unpaired portion extends for from 30 to 40 degrees on each side beyond the paired portion. Bender and Strauss (*Arch. Ophth.* 1937 19 765) reported 10 cases in which, as a result of defects in the optic radiations an unpaired crescentic or hemicrescentic vision existed in the periphery of the temporal field. They concluded that an unpaired peripheral scotoma indicates an early defect in the optic radiations, and that such a finding has localizing value in the early diagnosis of tumor of the brain.

It is the purpose of this article to substantiate these observations of Bender and Strauss with 5 verified cases of brain tumor and to emphasize the value of this sign as an aid in the practical localization of a pathological cerebral process.

In the first case, perimetric studies showed a distinct crescentic cut in the right field of vision without any changes in the central field. Operation in this patient uncovered a large meningioma in the

left parieto-occipital region. In the second case there was a crescentic cut in the left visual field and operation disclosed a large meningioma of the right parietal region. In the third patient, in whom a temporal crescentic defect in the left visual field suggested injury to the right optic radiation, a bone flap was turned down in the parieto-occipital region but the dura was not opened. Perimetric examination performed four weeks after the first surgical procedure showed an incongruous left homonymous hemianopsia. Subsequently the tumor was exposed and proved to be a well demarcated cystic astrocytoma deep in the right parieto-occipital region. In the fourth case a temporal crescentic defect in the right visual field resulted in uncovering a large cystic glioma of the left parietal area and, finally, in the fifth case a temporal crescentic defect in the left visual field with, as in the previously cited examples, no sign of changes in the central field was apparently induced by a glioblastoma multiforme of the right temporo-parietal area.

The author admits that no exact anatomic information may be derived from these cases as the position of the tumor itself may not tell the entire story that is cerebral tumors produce edema and other distant phenomena which may also cause disturbances in the fields of vision. However he believes that the 5 cases here reported bring out the importance of the temporal crescentic defect as an early localizing sign, and thinks that a 5 degree difference between the two fields should be regarded as significant.

JOHN W. BRENNAN, M.D.

Wright, R. E., and Stuart Harris, C. H.: The Penetration of Penicillin into the Eye. *Brit J Ophth.*, 1945 29 428

This article describes the clinical and biological techniques used in evaluating the penetration of penicillin into the eye. It is noted that the penicillin that reaches the aqueous humor after local use or intramuscular injection is of very low concentration. It is noted that the use of iontophoresis gives a far higher intraocular concentration, but the method of application is a technically difficult procedure. The procedure is described.

HUNTER H. ROMAIRE, M.D.

Davidson, M.: Compensation for Ocular Injuries in the United States. *Am J Ophth.* 1945 28 856

As is well known to those engaged in industrial work, there is a great discrepancy between the laws of the various states regarding compensation for an industrially damaged eye. The Federal Government itself operates with two standards in different departments. The range is so great that five times as much is given in some states as is awarded in others for the loss of an eye. This calls for standardization of benefits for permanent and temporary visual disability for facial disfigurement and for percentage of weekly wages to be paid out.

There are six main items which should be established

1 The amount that should be awarded for the loss of an eye, or loss of its use, in terms of percentage of the award for permanent total disability

2 The definition of loss of use of one eye and loss of use of both eyes (permanent total disability)

3 The definition of normal central visual acuity for distance and the degree of departure from normal that is subject to compensation

4 The method of dealing with partial loss of central visual acuity for distance

5 The method of dealing with the principal colateral or auxiliary functions of vision (muscles fields, accommodation)

6 The maximum deduction for temporary disability if any from the award for permanent damage to an eye

Each of these subjects is discussed in detail with illustrations of the inconsistent treatment in various states and much of the report of the American Medical Association Committee on Visual Economics is analyzed and criticized.

It is recommended that the average annual cost of compensation be taken as a standard and be made uniform for the country. The prevention of accidents is really the big problem and headway is being made in that direction.

WILLIAM A. MANN, M.D.

EAR

McCurdy, G. J.: Endaural Mastoidectomy Five Years Experience. *Laryngoscope* 1945 55 349.

This is a report of 122 cases of endaural mastoidectomy performed over a period of five years. Certain disadvantages are mentioned for the simple mastoidectomy such as persistent bleeding, the formation of unsightly scars and the difficulty in reaching tip cells in certain cases. Trauma to the temporal muscle occurs occasionally.

Among the advantages are continuous drainage during wound healing and the fact that the tympanic cells can be dealt with more easily. Postoperative care is reduced to a minimum and the scar is usually invisible. No packing is necessary in the depth of the wound.

There were no disadvantages in radical and modified radical cases, but there were several distinct advantages among them were better exposure of the entire mastoid areas, no necessity for plastic surgery at the end of the operation and the absence of postoperative packing.

JOHN F. DELANEY, M.D.

NOSE AND SINUSES

Griesman, B. L.: Structure of the External Nose. A Study from the Point of View of Plastic Surgery. *Arch. Otolaryng.* Chic., 1945 42 117

The author states that the final cosmetic result of a rhinoplasty depends not only on the surgical procedures but also on the influence of intrinsic and extrinsic stresses on the process of healing.

The force of mastication is the main physiological stress on the facial skeleton in the vertical and longi-

tudinal planes. The nasofrontal, malar zygomatic, and pterygoid buttresses transmit the chewing stress to the vault of the skull.

The nasal septum has a complex function in that the vomer seems to transmit chewing stress to the body of the sphenoid. The cranial portion of the septal cartilage and the upper lateral cartilages form a resilient arch to keep the nostrils open, and the caudal portion of the septal cartilage supports the nasal tip. In the typical rhinoplasty the lateral osteotomy interrupts in part the lines of force in the anterior or nasofrontal buttress. The act of chewing in the postoperative period tends to cause more callus to be formed along the sawcuts which, in turn may interfere with the desired cosmetic result. Therefore it is recommended that the chewing of hard or tough foods be omitted during the first six weeks following operation and that biting with the incisors be prohibited. JOHN R. LOOMAY, M.D.

MOUTH

Lawrence, E. A. and Bresina, P. S.: Carcinoma of the Oral Cavity. *J. Am. M. Ass.* 1915, 15: 10-1

Lawrence and Bresina report a series of 145 cases of carcinoma of the oral cavity seen at the New Haven Hospital, New Haven, Connecticut January 1, 1911 to December 31, 1910 inclusive.

The largest group of cancers from the point of view of numbers occurred in the hypopharynx and posterior tongue. Anatomically they include all tumors in the pharynx lying between the circumvallate papillae of the tongue and the extrinsic larynx. The tumors of the anterior part of the tongue include all which are anterior to the circumvallate papillae. The tumors on the floor of the mouth include those in the area bounded laterally and anteriorly by the inferior alveolus and medially by the tongue. The tumors of the alveolus include those in both upper and lower gum margins. The tumors of the buccal mucosa include those in the mucous membrane lining of the cheeks and inner lips. The tumors of the palate include those of both the soft and hard palates and the tumors of the tonsil include tumors originating in the tonsillar fossa. There were a few cancers of the oral pharynx that were so extensive and involved such a large area (palate, tonsil, base of the tongue and floor of the mouth, for example) that they were difficult to classify as to their point of origin. Therefore since they would have formed such a small group as to be completely meaningless, they were placed in the major groups according to where the bulk of the tumor lay.

The therapy of oral and pharyngeal carcinoma is a difficult and discouraging problem. There can be only rare individuals who are naive enough to believe that radiation therapy and surgery are ideal therapeutic instruments. Yet, until something better is discovered, these two methods remain our only hope of obtaining survivals in the treatment of this as well as of other cancer. Until that method

appears, attempts at improving our results must be directed not only toward the more intelligent use of these two instruments but also toward making them more available to the general public and practicing physicians at large, and toward educating the public and physicians in the early signs and symptoms of this disease. Perhaps it is incongruous to suggest, in face of the fact pointed out that there was no more delay in the failure group than in the successful one that early diagnosis is important. However it is a simple platitude that a small tumor is more easily and satisfactorily treated than a large one, and if the individuals harboring such tumors could be seen when the tumors are small there is no doubt that greater success would be obtained. Seven of the 16 patients with carcinoma of the hypopharynx stated at the time of admission that their chief complaint was a lump in the neck. In other words, more than 25 per cent of the patients in this group were complaining of something which indicated that for practical purposes the disease was beyond the curable stage. What would have happened if the tumor had been discovered when it was only 1 cm. in diameter?

The educational program must be intensified in the dental profession as well as in the medical profession so far as oral carcinoma is concerned. Thirty seven of the patients in this series had been seen first by a dentist. Ten of the 22 with alveolus tumors had been seen and treated by a dentist before being referred for medical care, and 8 of these had delayed for more than two months. One had been under active care for nearly a year and a half. If our primary objective were to find and treat the disease before the regional lymph nodes become involved, the salvage would be large. A specific example is shown by the tumors on the anterior part of the tongue. Only 2 of the 14 patients with lymph-node involvement survived five years whereas 3 of the 9 without node involvement were living and well at the end of the same period.

As far as therapy itself is concerned probably the cardinal point in successful management is attention to detail. The utmost care must be used in localizing the tumor and involved nodes, if present, in localizing the treatment ports, in directing the treatment beam precisely not only at the initial treatment but also at all other treatments, in management of the radiation reaction and in securing frequent follow-up examinations in the early post therapy months so that if an extension or recurrence appears further treatment can be initiated promptly. The problem of dosage is not complicated. If epidermoid carcinoma is to be destroyed, a dose of at least 5000 roentgens must be delivered into the tumor. This usually requires supplementary interstitial radon in addition to roentgen therapy. Ideally the x ray treatment should be administered in about twenty-one treatment days, and radon should be inserted when the tumor has regressed to its maximum degree. The authors believe that radiation should not be delivered so rapidly or so

extensively that it will produce a pronounced degree of tumor necrosis with infection because it is their impression that infection stimulates tumor growth.

BENJAMIN GOLDMAN, M.D.

NECK

Sandberg, I. R.: Dissection of the Cervical Lymph Node Regions for Metastasis from Malignant Tumors of the Lip, Oral Cavity and Pharynx. *Acta chir scand.*, 1945 92 99.

The lymph node regions to which cancer of the lip, mouth and pharynx first spreads are described and illustrated. The submental and submandibular regions and the superior and inferior deep cervical nodes are apt to be involved. Three operative methods are used for the surgery of these lymph gland metastases. The first consists of radical massive dissection of all the primary lymph nodes involved, the second of dissection of the submandibular region with or without that of the submental region, and the third of extirpation of single lymph nodes or groups of nodes. The latter method is justifiable only for purposes of diagnosis. The technique of operation is described in detail and illustrated.

A discussion is given of 73 cases of lymph gland metastases operated on at the Karolinska Hospital in Stockholm. 93 operations were performed in these cases.

Fifty-six of the patients were men and 17 were women. The youngest patient was 35 years of age, the oldest 80. 75 per cent of the patients were over 50 years of age. 41 per cent over 60 and 18

per cent over 70. A table is given showing the site of the primary tumors and the nature of the operations.

In radical dissection, especially in advanced cases it is almost impossible to avoid injury of the nerves. There is often transitory paresis of the facial nerve and sometimes permanent injury. The accessory nerve is also quite frequently injured which results in partial paralysis of the trapezius muscle. Dissection of the internal jugular vein is sometimes slow and difficult and rupture of the wall of the vessel may cause fatal air embolism.

In this series of 73 cases there was only 1 death (1.4% mortality). The patient was a man of 54 years who died of anoxemia resulting from laryngeal edema. Among the 39 massive radical extirpations performed on 37 patients the mortality was 2.7 per cent. The mortality at the Zurich Clinic from 1927 to 1936 was 14.4 per cent (13 deaths among 113 patients) but the massive radical method was used in most of these cases. The average stay in the hospital for the author's cases was 10.5 days. This was perhaps shorter than usual because most of the patients were removed to the Radiumhemmet for postoperative irradiation. It is hard to determine by histological examination whether a piece of tissue has been irradiated or not for the changes caused by irradiation may also occur spontaneously.

It is difficult to judge the final results in this series of cases as the time since operation has not been long enough. But among 53 patients who were examined a year after operation, 31 were alive and free of signs of recurrence. 8 showed recurrence. 12 had died from cancer and 2 had died from other diseases.

AUDREY G. MORGAN, M.D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Denny Brown, D., and Doherty M. M.: Effects of Transient Stretching of the Peripheral Nerve. *Arch. Nerv. Psychiat. Chic.*, 1945, 54: 116

Dense intraneural fibrosis of the peripheral nerve without anatomic loss of continuity is seen in modern warfare. It is due in some way to the passage in close proximity to the nerve of a projectile traveling at high velocity. The authors previously investigated the pseudoneuroma produced by percussion of a peripheral nerve which does not conform to the lesion under discussion. Because of the great and rapid distortion of soft tissues produced by the impact of a high velocity bullet, the possibility that this caused a sudden longitudinal stretch in the nerve was investigated.

The reproduction of such a rapid longitudinal stretch by experimental methods is difficult, and finally it was decided to produce the stretch by means of grasping the nerve in the gloved fingers. The peroneal nerve of the cat was used and the animal was placed under pentobarbital anesthesia. The nerve was marked at measured intervals and the extent of the stretch was recorded in percentage terms. Survival ranged from 5 to 140 days. A table with the essential points is provided. When the nerve was stretched until the distance between the markers was increased 100 per cent there was often no sign of hemorrhage within it and only slight weakness was noted when the animal recovered from anesthesia. Full motor power returned within four to ten days. If stretching was continued beyond 100 per cent of the distance between the markers a sharp "crack" or "snap" occurred. A small white hernia of nerve fibers was seen next to the main nerve bundle and if tension was persisted in the whole nerve bulged out through the sheath. The resistance of the nerve to further tension was then much reduced. The herniation was always followed by complete paralysis. The smallest hernia was allowed to remain 141 days, recovery commenced about the twenty first day and was complete in 48 days. On section a large pseudoneuroma was found. In the early stage of a small hernia rupture of the epineurial vessels and thrombosis of the small arterioles were found on section.

The difference between benign pseudoneuroma and true neuroma depended on the degree of disorganization of the architecture of the nerve bundle. Unaided recovery is to be expected from the pseudoneuroma but not from the true neuroma. A test for perineurial continuity is therefore of practical importance. The injection of saline solution along the neural fasciculus is the most useful test and the one most commonly employed. The true neuroma is also adherent to the surrounding structures, whereas the pseudoneuroma presents a smooth, unbroken

surface. Unfortunately high velocity bullets often result in scar tissue in the proximity of the nerve which, whether it contains a pseudoneuroma or not, may be adherent to the surrounding structures.
ANASTAS VASSAROVICH, M.D.

Ward, R. L. and Mason, A. B.: Polyneuropathy after Jungle Sores. *Brit. M. J.* 1945, 2: 59

Among the many appalling geographical and climatic hardships in the Burmese jungle were jungle sores which were multiple indolent ulcers developing usually on the lower leg or forearm. In 21 patients who had had jungle sores peripheral polyneuropathy was found. In all but 1 the sores had healed before admission to the hospital on account of the neuropathy. The typical ulcer was about 3/4 inch in diameter and circular or oval in shape and it presented a necrotic, sloughing punched-out appearance.

The clinical course was rather typical. In 16 cases the first symptom of nervous involvement was blurring of the vision which came on about 7 weeks after the jungle sores began. There was disturbance of sensation in all of the cases although in the mild ones this amounted only to paresthesia. There was occasional difficulty in writing and in walking. In severe cases there was progressive weakness of the limbs to the shoulders or hips. In some the gait deteriorated to the point where walking was impossible. According to the severity of the case there was anesthesia and trophic and ataxia. A table with the principal signs and symptoms is provided.

The etiology of the polyneuropathy was of particular interest. Chemical poison could be excluded. When polyneuropathy was due to vitamin B deficiency it responded to vitamin therapy. In contrast to these cases a toxin was suspected and diphtheria bacilli were isolated from the sores. The paralysis of accommodation also gave support to this view. There was no relation between the site of the sores and the limbs in which the polyneuropathy developed. The toxin could not be obtained. Ordinary diphtheritic infection was a very unlikely possibility.

Because of the circumstance no laboratory investigations were possible and the cases are presented from the purely clinical standpoint.

ANASTAS VASSAROVICH, M.D.

BRAIN AND ITS COVERINGS CRANIAL NERVES

Michaelsson E.: Pneumocephalus. *Acta chir. et med.* 1943, 29: 3

In external pneumocephalus the air is situated between the skin and the skull. In internal pneumocephalus it is found inside of the skull. Pneumocephalus generally results from fracture or penetrating injuries of the skull, although it may be caused by chronic inflammation such as tubercu-

low or syphilis. The fractures that most frequently cause it are those of the frontal bone. The most common type of pneumocephalus is the subdural. The symptoms are rather indefinite, being those of cerebral pressure in general. Diagnosis by roentgen examination is now quite simple. There are two dangers to be feared: infection and cerebral pressure. Dandy advocates immediate operation in all cases on account of these dangers.

The author describes a case in a young man of 16 years who fell from his bicycle on July 12, 1941 and incurred a fracture of the right frontal and ethmoid bones. On admission to the hospital there was bleeding from the nose but not from the ears and the only apparent injury was a cut 3 cm. long in the right frontal region which was sutured. He had apparently recovered completely when he was discharged on the 4th of August. No roentgen examination of the skull was made.

About two weeks later he began to have a discharge of fluid from the nose. Roentgen examination showed a fracture of the frontal bone which probably extended into the ethmoid and there was air underneath the dura and throughout the ventricles. He was put at rest in bed and later sulfonamide was given. He had a subfebrile temperature with occasional peaks to 38.6°C and a leucocyte count ranging from 12,000 to 17,000. On September 18 the right frontal lobe was exposed, trepanation was done, and air and liquid were aspirated from a softened portion of the right frontal lobe over which the dura was thin and flabby, although there was no definite defect in it. A graft of fascia lata was placed over the changed part of the dura and the patient made an uneventful recovery.

As there was no real defect in the dura the good results could hardly be credited to the fascia transplant. It is possible that the aspiration of fluid and air brought about the recovery.

AUDREY G. MORGAN, M.D.

Gaynor W. C. and Gurwitz J.: Experiences with 154 Penetrating Wounds of the Head. *Ann. Surg.* 1945 122: 12.

A series of 156 consecutive craniotomies performed in a forward hospital for penetrating wounds of the head are reported. The dura was intact in 19 cases and penetrated in 137. The average time in interval between injury and definitive treatment was twelve hours. The authors agree that these patients can be transported better before operation than after but they believe that the delay (up to seventy-two hours) required to get the injured back to a base hospital would not be tolerated by many. The forward evacuation hospital presents the ideal place for this surgery since it is the most forward site where adequate neurosurgical facilities are available and a roentgenologist is present.

The management of these cases is described in detail. It conforms in most aspects with that recently reported by other workers. Endotracheal ether anesthesia was found to be the one of choice

after extensive experience with local anesthesia and intravenous pentothal.

The authors found a long magnet tip to be very useful in removing metallic foreign bodies. The latter were consistently found to be contaminated when cultured and it is believed that all metallic as well as bony foreign bodies should be removed.

The operative mortality was 10.8 per cent (17 deaths). There were 5 cases in which the ventricle was opened and 2 of the patients died. The frontal sinuses were involved in 26 cases. The sinus walls and mucous membrane were removed which obliterated them. The results were stated to be satisfactory. There was no selection of cases except in times of heavy fighting when there might be several head cases waiting. In such instances priority was given to the patients with the best chance for survival and return of function. Thirty-four other than those included in this series were seen in the receiving tent and 33 of these died promptly.

The wound tract was dusted with sulfanilamide in the early part of the series, and filled with from 7,500 to 20,000 units of penicillin in the later cases. The dura was closed in all cases, a graft being used in most instances. Fascia lata was used in a few cases but temporal fascia, pericranium or galea was used in the majority. Cadaver dura was used in 33 cases with no early untoward results. It is preserved in 10 per cent formalin for forty-eight hours and then in 70 per cent alcohol indefinitely.

Two-thirds of the patients had other wounds as well. Head wounds can generally wait for treatment better than extensive wounds of the abdomen, chest or extremities. The staging of multiple operations is better than doing all of the surgery at once. Nine cases operated upon in stages resulted in 2 deaths, while 5 cases operated upon in one stage resulted in 3 deaths. HENRY A. SMITH, M.D.

Redlich F. C. and Dorsey J. F.: Dental of Blindness by Patients with Cerebral Disease. *Arch. Neurol. Psychiat.* 1945 53: 407.

Detailed reports are given of 6 patients who were blind but who denied their blindness. The patients all had diffuse cerebral lesions and showed mental deterioration with disorientation, impairment of recent memory, and amnesic aphasia. The underlying organic disease was diabetic retinopathy in 1 case, optic atrophy in 1 case, and bilateral hemianopsia due to tumor or vascular lesions in 4 cases.

The authors also review the literature. In their opinion mental deterioration alone does not explain the syndrome; they believe that the interruptions of reverberating circuits between the thalamus and the sensory cortex constitute the outstanding etiological factor. ADRIEN VERBAUGHEM, M.D.

Dandy W. E.: Diagnosis and Treatment of Strictures of the Aqueduct of Sylvius (Causing Hydrocephalus). *Arch. Surg.* 1945 51: 1.

The symptoms of hydrocephalus may appear in infants or in older children. In infancy 95 per cent

If the cases are due to congenital stricture of the aqueduct of Sylvius and in childhood 95 per cent are due to tumors. In infants cases are seen also in which hydrocephalus occurs as the result of occlusion of the foramina of Magendie and Luschka. In both aqueduct and foramen obstruction, the dye test with phenolsulfonphthalein will show it. There is, however, one differential point in obstruction of the aqueduct the inion is low whereas in obstruction of the foramina of Magendie and Luschka the inion is high. This is due to the location of the obstruction—in one the tentorium is pushed upward and in the other downward. In children and adults without localizing cerebellar signs, ventriculography may have to be done to localize the site of the obstruction. In most cases in which complete filling of the ventricular system has been accomplished, an accurate localization of the point of obstruction is possible. The height of the inion has been used for diagnosis in 5 cases without ventriculography and operation, in which there was a stricture of the aqueduct.

Ventriculostomy has been the operation of choice in dealing with these cases. Cerebrospinal fluid is short-circuited from the third ventricle into the cisterns at the optic chiasm and cerebral peduncles. It appears to be essential to open the floor and not the roof of the third ventricle. Two types of ventriculostomy, through the floor have been employed. The author in 1932 proposed an anterior approach through a small supraorbital incision. This was not always satisfactory because an optic nerve had to be sacrificed to gain exposure to the floor of the ventricle, and because the fluid was often improperly absorbed. The procedures advocated by White Stookey and Scarf and by Torkildsen are not considered satisfactory.

It is now proposed that a lateral approach is more likely to satisfy all the conditions. With the child's head in a plaster cast, the right temporal region is opened through a curved incision. Through a small bony opening the lateral ventricle is tapped and the temporal lobe elevated from the middle fossa. The edge of the tentorium and the oculomotor nerve are brought into view. The bulging thin floor of the third ventricle is seen and is opened with a nerve knife, the opening is then enlarged with alligator forceps.

Twenty nine patients over 1 year of age were treated by this method, 5 in the first 5 years of life, 5 in the second 5 years, 15 between the tenth and twentieth years and 4 after the twentieth year. The oldest patient was 45. Thirty-six ventriculostomies were performed on these 29 patients (in some the opening had subsequently closed). There was 1 operative death, while 24 patients are living and cured.

Sixty-three patients under 1 year of age were operated on by this method, 10 of whom died in the hospital and 53 survived. Only 5 are perfectly healthy children, some have died since they left the hospital and others have mental or visual defects.

When the head is not more than from 30 to 52 cm. in diameter the operation is probably worth while.

ADRIAN V. FERENCZ, M.D.

Ingraham, F. D., Bailey, O. T., and Cobb, C. A., Jr.: Fibrin Film. *J. Am. Med. Ass.* 1945 28 1033.

Neurosurgeons have long sought a suitable material with which to cover the brain and to replace dura mater, but so far none has been really satisfactory. The substance, fibrin film, may be the answer to the problem. Its discovery and use were incidental to a protracted program of research undertaken at Harvard Medical School on the "Studies of Plasma Proteins" and this paper is No. 37 in the series. Large quantities of fibrinogen and thrombin became available during the program and from these proteins it has been possible to prepare fibrin film.

A great many films can be produced but this one was selected for the following reasons:

- 1 When this film is placed over the brain of man, it is gradually replaced by a neomembrane of fibrous tissue without the formation of meningeal-cerebral adhesions.

- 2 It is possible to sterilize fibrin film in the final glass ampoule by steam under pressure.

- 3 As judged by animal experiments the film is largely removed in 3 months and completely removed in 6.

- 4 All patients remained free of symptoms referable to fibrin film.

The film has been used in a total of 94 neurosurgical cases presenting a wide variety of lesions.

From the technical standpoint the film is easy to use. It is packed in a glass ampoule from which it is removed under sterile conditions in a dry and brittle state. After it is soaked in saline solution for 15 minutes the paper wrapper is removed and the film placed in cool saline solution until it is required. In this state it is soft, pliable, elastic, transparent, and easy to handle provided it is kept moist. It is rarely necessary to secure the film in place over the brain, although this may be done if desired.

ADRIAN V. FERENCZ, M.D.

Shaloun, E. S.: Purulent Meningitis: Use of Hypertonic Solutions in Treatment. *Lancet* Lond 1945, 249:36.

Purulent meningitis may lead to adhesive obstruction at the foramen magnum and hypertonic parenteral fluids may relieve it, this is the main argument of this closely reasoned paper. The ideas are developed from 11 cases of purulent meningitis seen in the last five months. In 8 cases, and probably in the ninth case the pneumococcus was isolated and in another case the streptococcus pyogenes was found. The remaining case also revealed purulent spinal fluid but no organism was identified even though the staphylococcus aureus was isolated from the wound and from the blood.

The theory of obstruction at the foramen magnum was deduced from two facts: first, early in the meningitis, spinal fluid pressures in the manometer

were of the order of 300 mm. r. ver. her as in later punctures a pressure of 300 mm. was rarely obtained. Second during the individual puncture rather late in the disease there was a progressive slowing in the rate of fluid in the manometer. Clinical and mechanical grounds that were taken to be due to the descent of the cerebellum and the folds into the foramen magnum. A close similarity to these findings exists when spinal punctures are done on brain tumors with increased intracranial pressure. There is a detailed description of the clinical cases on which these assumptions are based.

The clinical significance is twofold: (1) the obstruction at the foramen magnum may give rise to a picture of increased intracranial pressure with stupor, Cheyne-Stokes respiration and slowing of the pulse to 60 per min. and (2) the obstruction also prevents the entrance of therapeutic agents such as penicillin and their reaching the cranial cavity after they have been inserted into the lumbar subarachnoid space.

Experiments were carried out on 2 cases with a view to relieving the obstruction and facilitating the entrance of penicillin from the spinal into the cranial subarachnoid space. The intracranial use of 20 per cent dextrose in physiological sodium chloride was used to decrease the intracranial pressure and to relieve the foramen obstruction and in this way allow free access of the penicillin from below.

Treatment consisted of full doses of sulfadiazine in this case sulfamezathine by mouth. This was considered an essential part of the treatment. Penicillin and hypertonic solutions were given intracranially in calculated doses. The penicillin and the hypertonic solutions were mixed together and injected every three hours. Adults receiving 15,000 units and children a suitably reduced dosage. All cases received 4,000 units of penicillin intrathecally every twenty-four hours. Larger doses do not seem warranted because in 11 cases with initial attack and 15 with relapses, sterile cultures of spinal fluid and corresponding clinical improvement were uniformly obtained in twenty-four hours.

Three deaths occurred—all in pneumococcal cases—and in only 1 did the examination show evidence of active meningitis. In this case pus was found over both cerebral hemispheres with only two foci of pus below the tentorium. One death was due to bilateral basal bronchopneumonia which was considered to have preceded the meningitis. The third death occurred during a convulsive seizure but very little evidence of meningitis was found at autopsy.

ARTHUR VERBEEK, M.D.

SYMPATHETIC NERVES

Koster E. F.: Adrenosympathetic Syndrome Associated with Paraganglioma of the Organ of Zuckerkandl. *Ohio M. J.*, 1945 41: 739

The patient was a thirty-four-year-old female with a three-year history of recurrent episodes of head

ache, nausea and vomiting, insomnia, irritability, flushing and sweating with moderate prostration. During an attack examination revealed a blood pressure of 210/110 and a pulse rate of 120. Precipitous activity was increased but the heart sounds were normal and there were no signs of cardiac enlargement or decompensation. The specific gravity of the urine was 1.023 and the qualitative level of the albumin in the urine was 4+.

The neck was rigid and lumbar puncture revealed a slightly spinal fluid under slightly increased pressure. There was a positive Babinski reflex on the right and the right pupil was larger than the left. Bilateral papilledema was present.

The patient rapidly developed a right hemiparesis passed into coma and died within thirty-six hours of admission to the hospital.

Autopsy revealed an extensive intraventricular and subarachnoid hemorrhage. Cross sections of the brain and examination of the meningeal vessels failed to reveal the origin of the hemorrhage. A small encapsulated tumor (4 by 3 by 2 cm.) was found attached to the anterior surface of the noma immediately caudal to the renal arteries. Microscopic diagnosis revealed benign paraganglioma of the organ of Zuckerkandl.

The symptoms of this patient were believed to be produced by the periodic discharge of adrenaline or a catecholamine substance into the general circulation. Autopsy revealed an associated moderate degree of renal arterial sclerosis. There is a possibility that the hypertension was associated with the renal lesion rather than with the tumor.

HENRY A. SLENNER, M.D.

Kirtley J. A. Jr.: Experiences with Sympathectomy in Peripheral Lesions. *Ann. Surg.*, 1945 122: 39.

The war has demonstrated a variety of indications for sympathectomy in peripheral lesions. This is borne out by a report from a general hospital in a Theater of Operations in the period from March to September 1944. The operations were performed for the following conditions: tender feet, arterial injuries, post-traumatic vasospastic conditions, obliterative vascular disease and causalgia. All were lesions of the lower extremities.

Twenty-three operations were performed on 27 patients with trench feet. The interval between exposure and operation varied between two and seven months. Repeated lumbar sympathectomy had been tried but was found to be successful only in late cases with pronounced vasospasm. Removal of the second and third lumbar sympathetic ganglia made it possible to return 50 per cent of the patients to duty within a month. The best results were obtained in the patients with severe hyperhidrosis, maceration and secondary infection.

In the 20 cases with injuries of the main arteries in the leg especially the popliteal artery, the sympathectomy was limb-saving in some and frequently permitted amputation at a lower level. Patients

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Brantigan, O. C., Aycock, T. B., Hoffman, R., and Welch, H. J.: Relaxing Thoracoplasty. *J Thorac Surg* 9:15, 14, 237

In pulmonary tuberculosis three general types of lungs with corresponding bronchi can be recognized. In one type of lung, the bronchial condition leads to increased intrapulmonary pressure or increased pressure within the tuberculous lesion. It is one in which, either because of organic factors or muscular spasm involving the bronchial musculature, air freely enters into the alveoli during inspiration but its escape is delayed on expiration. In the second type (as opposed to increased intrapulmonary pressure) a form of bronchial condition occurs which leads to a hypotensive lung. In this type the bronchus may be partially or completely occluded by organic disease or its secretions, or by a decrease in the tone of the bronchial musculature, thus permitting only a minimal amount of air into the alveoli, but allowing this air to escape easily. In the third type of lung, the bronchi may be free of organic or spasmodic involvement. Air is permitted to flow freely in and out of the alveoli and bronchial tree. This produces a lung with normal intrapulmonary pressures.

It appeared evident to the authors that if the thoracic cage could be relaxed when the contracting phase of bronchial disease occurred, perhaps the lung could contract easily because the restraining force of a rigid thoracic cage had been removed. The same would be true if healing was taking place by scar tissue contraction. This contraction would be encouraged and it would be more likely to remain until the healing was complete. The belief that a relaxed thoracic cage might be more desirable than a rigid collapsed thoracic cage is strengthened by the evidence that collapse of the lung in itself does not necessarily mean healing nor cavity closure.

With these principles in mind, an operative procedure, which is a modification of Monaldi's operation, was undertaken primarily for patients with tension cavities and for those with extensive disease from the apex to the base on one side but without giant cavities. By interrupting the muscles of the superior aperture paralyzing the diaphragm, and doing costectomies along the dominant line the chest is made static and the lung is freed from respiratory trauma. The operation is divided into 5 stages. If this series of operations fails to bring about an arrest of the disease, the operation can be converted into a standard thoracoplasty. Patients who are not suitable candidates for the standard thoracoplasty might thus be brought safely to such a condition.

The operative procedure was carried out on 33 patients. Their ages varied from 19 to 55 years with the greatest number occurring between the ages

of 30 and 40 years. The longest period of observation was approximately two years and the shortest ten months. In 3 patients the relaxing thoracoplasty was converted into a standard thoracoplasty and, of these, 1 died. Five deaths occurred in the series.

It appears that the patient with a giant cavity is not a suitable candidate for this operative procedure unless one is content with bringing the lesion and the patient to a condition in which the relaxing thoracoplasty can be converted into a standard thoracoplasty. Whether this operative procedure will adequately arrest the disease in the tension type of lung has not been conclusively refuted or affirmed. The patient with a concomitant disease or the one with some collapse of the contralateral lung is a good candidate for this operation. It also appears likely that the patient afflicted with the disease from the apex to the base on one side, but without giant cavities is an ideal candidate for this operative procedure rather than for a complete standard type of thoracoplasty. The individual who has a pulmonary lesion which can be controlled by a one-stage standard thoracoplasty certainly should not be subjected to this type of operative procedure.

On the whole, results are encouraging and certainly worthy of further study. Many patients who formerly had no hope of the disease being arrested are now brought within the realm of surgical treatment. Only time will determine the worth of this operative procedure as well as its indications.

JOSEPH E. NAKAT, M.D.

Engelstad, R. B.: On the Treatment of Carcinoma Mammæ. *Acta chir scand* 94: 87, 545.

It is hard to compare statistics for cancer from different hospitals because of the differences in classification and methods of treatment. The author presents the statistics of 553 cases from the Norwegian Radium Hospital, pointing out that the results are unfavorably influenced by the fact that so large a proportion of the cases were in the late stages, because of the nature of this hospital. Notwithstanding this fact, the patients had 3 years of freedom from recurrence in 94.4 per cent of the cases and 5 years of freedom from recurrence in 92.5 per cent of the cases in stage I. The 3 year and 5 year figures for freedom from recurrence in stage II were 59.1 and 52.2 per cent, respectively. The differences in treatment methods are shown in this group by the fact that the 3 year and 5 year survivals after post-operative radium treatment were 65.4 and 64.5 per cent, respectively while after other methods of treatment they were 49.2 and 48.5 per cent, respectively. The figures for 3 and 5 year freedom from symptoms in stage III were 10 and 8 per cent, respectively and in stage IV 8.4 and 8.2 per cent, respectively.

The conclusion is reached that irradiation treatment cannot replace surgery but that it is a valuable supplement to it. It is believed that the best results can be obtained by giving irradiation treatment postoperatively in one series in as large doses as can be given without injuring the normal tissues and without producing too great leucopenia in the blood. Radium has been found superior to roentgen rays for postoperative treatment.

Local recurrences were for the most part treated by the application of radium. Lymph node metastases, with telradium or roentgen irradiation and skeletal metastases with roentgen irradiation in doses of from 7,000 to 4,000 roentgens. Visceral metastases were given palliative roentgen irradiation in a few cases. There was hilar involvement in 7 per cent of the cases, 24.5 per cent of these were free from recurrence after three years.

The greatest number of cases of cancer of the breast are seen in the age groups from 40 to 49 and from 50 to 59, that is around and immediately after the menopause. This shows the importance of hormonal conditions in the development of these tumors. Further study should be devoted to hormonal influences and to the histological types of these cancers. The prognosis is unusually bad when cancer of the breast coincides with pregnancy or lactation and it is worse in the younger age groups than in the older ones.

AUDREY G. MORRAN, M.D.

TRACHEA, LUNGS, AND PLEURA

Koffman H. J. F. and Crellin J. A.: Penicillin in Suppurative Diseases of the Lungs Due to Streptococcus Hemolyticus. *Ann Int M.*, 1945 33 135

Two patients with lung abscess which developed in the course of sulfonamide resistant streptococcus hemolyticus pneumonia were successfully treated by the authors with parenteral penicillin. The number of days of penicillin therapy 14 and 24, and the total dosage of 1,475,000 and 3,020,000 units are indicative of absorption of penicillin through thin walled cavities when administered over a sufficient period of time. The sputum in the 2 patients became negative for hemolytic streptococcus in three days and two days respectively. Complete healing demonstrated by roentgenogram occurred in twenty-six and thirty-four days respectively.

Intrapleural injection of penicillin supported by intravenous and intramuscular use of the drug obviated thoracotomy in 4 patients with streptococcus hemolyticus empyema, 2 being classified as sulfonamide resistant and the other 2 being considered moribund.

There was no evidence of reinfection or recurrence and aspirated pleural fluid remained sterile after from 24 to 36 hours, when the intrapleural treatment was supplemented by intravenous and later intramuscular penicillin. One patient receiving only intrapleural penicillin retained an infected pleural space until the sixth day after treatment was started

which would indicate that success or failure may hinge upon the supplemental parenteral administration of penicillin.

Residual fibrosis and subjective slight dyspnea necessitated the return to a limited duty status in 1 patient a seaman who had had repeated infections with periodic asthma since the age of four. The 3 others returned to a full duty status in 125, 146 and 151 days respectively.

STEPHEN A. ZIEMAN, M.D.

Rudensky H. Sprong, D. H. Jr. and Woods, C. C.: The Treatment of Empyema. *J Am M Ass* 1945 128 573

The addition of sulfonamides and penicillin to our therapeutic armamentarium has considerably improved the results of the treatment of empyema. Five cases are reported in this study 3 of which were putrid empyemas following ruptured lung abscesses. The patients were treated with sulfadiazine and penicillin administered intramuscularly and intrapleurally following thoracentesis. This combination has proved beneficial in mixed infections both aerobic and anaerobic. No untoward effects were noted from repeated thoracentesis. One case of postpneumonic empyema was treated with penicillin intramuscularly and intrapleurally and another case caused by staphylococcus (albus and aureus) was treated only by the intrapleural administration of from 25,000 to 50,000 units of penicillin in 100 to 200 c.c. of sterile saline solution. The instillation of penicillin was preceded by thorough aspiration of the pus.

One patient who suffered from a pyopneumothorax secondary to osteomyelitis of the sixth and seventh ribs yielded, on aspiration, 150 c.c. of thick, greenish foul pus which on culture revealed the proteus vulgaris and the staphylococcus aureus. Treatment consisted of sulfadiazine given orally and repeated irrigations of the pleural cavity with a 1:3,500 dilution of fresh aqueous azochloramid. The patient's temperature became normal after 9 days and he made a rapid recovery within the next few weeks.

ARTHUR J. LEXER, M.D.

Healy M. J., Jr. and Katz, H. L.: Penicillin for Empyema. *J Am M Ass*, 1945 128 568.

Five patients with empyema were treated with aspirations and intrapleural instillations of penicillin. The average dosage of penicillin ranged from 35,000 to 50,000 units in 100 c.c. of sterile saline solution which was instilled into the pleural cavity after thorough aspiration of the pus and occasional irrigation with sterile saline solution. The procedure was usually repeated on alternate days and the duration of treatment depended on the clinical response. Patients who were believed to have unresolved pneumonia or other complications received also an average of from 20,000 to 25,000 units of penicillin by the intramuscular route. Culture of the pus revealed the nonhemolytic staphylococcus aureus in 3 cases, the pneumococcus (type 3) in 1 case, the pneumo-

lytic streptococcus in 1 case and mixed infection of the nonhemolytic streptococcus and the hemolytic staphylococcus aureus in 1 case.

It is stressed that the treatment should be instituted at the earliest possible moment and that therapy need not await the results of bacteriological culture since the organisms commonly causing empyema are susceptible to penicillin. Thoracentesis should be performed at the lowest point of the cavity with a large gauge needle (15 or 17) preferably under fluoroscopic control and should be repeated until no pus reforms but a small amount of thin, sterile serous fluid is absorbed by the patient in a short time.

The acute episode of empyema was well controlled in all 5 cases. One patient suffering from an extensive empyema, had an acute flare-up after arrest of the disease for four months, which again was promptly controlled by penicillin. However, in this case extensive pleural thickening made further surgery advisable, in order to obliterate the chronic cavity. Three cases showed only a minimal amount of pleural thickening as evidenced by roentgenograms, while 1 case showed no thickening at all. The vital capacity in all 4 cases was undiminished and all 4 patients returned to active military duty within a few months. *Arthur J. Lassar, M.D.*

HEART AND PERICARDIUM

Roscoe C. D.: Heart Injuries; a Report of 3 Cases. Texas J. M. 945, 41, 5

Injuries of the heart are usually penetrating knife and bullet wounds of the chest and heart. The scarcity of cases of nonpenetrating heart trauma in the literature leads one to believe that it occurs rarely. This article was published to arouse interest in traumatic cardiac lesions and to stress the importance of considering possible injury to the heart in all cases of penetrating chest wounds, or direct or indirect trauma to the heart and great vessels in the absence of visible external damage to the chest wall. If we are looking for cardiac injuries we may find those that occur and discover that they are not as rare as suspected. Fortunately most chest contusions produce few functional disturbances, and those produced are usually not recognized.

We usually consider the thoracic cage a perfect armor for the heart and believe the heart to be immune to the usual injuries to which the rest of the body is subjected. The heart, however, lies behind the sternum, buttressed against the thoracic vertebra, and is vulnerable to compression forces applied to the chest. Brady and Kahn have emphasized that no prognosis of a traumatic heart case should be given without considering the following: (1) the physical and psychic condition of the patient prior to his injury, (2) the type, site and severity of the injury, (3) the immediate effects of injury both objective and subjective, (4) the bridging symptoms, (5) the time interval between the injury and the appearance of the disease, and (6) the diagnosis

of the disease, its mode of onset, the site of injury and its course. With penetrating wounds of the chest one should suspect heart tamponade, the signs and symptoms of which are: (1) the patient is usually free from symptoms for several minutes after the wound has been received (able to walk several blocks & fight on), (2) external bleeding stops as the tamponade forms, (3) marked circulatory collapse, which is out of proportion to the blood lost, (4) distant heart sounds muffled and weak (slushing may be heard), (5) weak or absent pulse, (6) low arterial blood pressure, (7) raised venous pressure (from 200 to 300 mm. Hg) with prominent distended neck veins, (8) fluoroscopic examination shows diminution or absence of cardiac pulsations (quiet heart) and (9) marked dyspnea, pallor, cyanosis, or unconsciousness. As heart tamponade is the most common cause of death in heart injuries, the clinician should be able to make the diagnosis and administer conservative emergency treatment. The treatment of penetrating heart wounds as directed by the United States Army is: (1) to aspirate blood from the pericardium, (2) to repeat this if there is recurrence, and (3) to operate if another recurrence takes place.

If lateral chest pressure is applied, ribs are fractured but the heart is rarely damaged. Posterior chest pressure rarely causes any heart damage but anterior force will do so. The force received by the patient depends on the size and weight of the object and its momentum. Anterior and posterior application of force & compression of the heart may cause injury to any chamber of the heart. Bright and Beck believe that all chambers of the heart may be injured by direct trauma. Bilderbeck believes that one possible cause of heart rupture is a sudden compression of the right auricle which becomes engorged because the patient holds his breath in deep inspiration just before a blow is received. White and Glendy believe the heart-chamber distention at the end of diastole or early systole is important in heart rupture. Lewis states that with deep inspiration and a closed glottis the heart dilates markedly and remains in this state as long as inspiration is maintained. The right auricle is most susceptible because of its anatomical relation to the anterior chest wall. This was confirmed by Gouley in whose series 38 cases showed an injured right auricle. The left ventricle is placed deeper in the chest, is better protected, and is a more robust, stronger muscle than the auricle; therefore, it escapes injury. It was damaged in only 1 case. The left auricle was injured in 16 cases and the right ventricle in only 4.

Children and young adults are more likely to have heart damage without external evidence on the chest. Pathologists say the chest wall really is injured in these cases if care is taken to look at the inner aspect where hemorrhage may be found in the interspaces. Persons in middle life do not have heart injuries without damage to the chest wall. Coronary thrombosis due to trauma to the chest is

never found in children and young adults. Coronary thrombosis is found in older people as is a disease of middle life and of older people with atherosclerosis.

In injuries of the lower one half of the sternum and the adjacent sixth, seventh, eighth and ninth ribs on the right side we may expect to find hematomas of the right auricle and injury of the inferior vena cava, diaphragm and liver with immediate death. If the upper half of the sternum with or without the adjacent ribs is damaged there should be annular damage.

Suspicion of heart injury with fluoroscopic examination electrocardiographic studies and careful follow-up should lead to the diagnosis of more cardiac injuries. Beck mentions that the development of the tic tac rhythm is suggestive in suspected cases.

The author presents 3 case reports of cardiac injury. The first was a ruptured aorta originating at a tiny atheromatous plaque at the right posterior aortic sinus in a twenty-six year-old male who was straining to lift a very heavy weight. It was believed that the original tear extended through about half the thickness of the media as this patient did not die until five days after the initial injury when he suddenly developed cardiac tamponade from a hemorrhage into the pericardial sac.

The second case was that of a twenty-seven year old negroess who was stabbed in the chest above the heart from her initial injury only to develop a large aneurysm of the heart presumably from damage to the anterior descending branch of the left coronary artery. She died because of the heart condition nine months after her initial injury.

The third case was that of a forty-four year-old white female who developed myocardial insufficiency and died four years after undergoing extensive x ray therapy over the heart for a breast tumor on the left side. The pathological examination revealed an x ray myocarditis with atrophy of the heart and chest wall.

ROBERT R. BIGGLOW M D

ESOPHAGUS AND MEDIASTINUM

Wason, P P: Incidence of Esophageal Disease in Negroes. *South M J* 1945 38 453

Comparison of the relative frequency of the occurrence of diseases in various races has always been an interesting study. At times variation in the incidence of diseases has been attributed to racial characteristics when environmental and economic conditions may have been the determining factors. In other instances apparent dissimilarity in the occurrence of certain diseases may have resulted from difference in the density of population of various races.

The study of the comparative incidence of esophageal disease in white and in negro patients was prompted by a letter of inquiry from a colleague in an Army hospital concerning a negro whom he had

TABLE I RACIAL COMPARISON OF THE INCIDENCE OF ESOPHAGEAL DISEASE AT THE MEDICAL COLLEGE OF VIRGINIA HOSPITAL 1936-1944

Name of Disease	Number of White	Patients Negro
Carcinoma	67	24
Cardiospasm	38	16
Diverticulum	13	0
Dysphagia functional or hysterical	0	1
Esophagitis	4	0
Foreign body	102	40
Hernia	63	4
Mucellaneous lesions	4	0
Polyps	7	0
Structures (congenital)	29	33
Varices	10	3
Negative esophagoscopic examinations	4	0
	30	11
Total	393	130
Grand Total		523

found to be suffering from cardiospasm. Previous experience and review of the available literature had suggested that cardiospasm was rarely encountered in the negro race.

It seems therefore that lesions of the esophagus which may have their origin in congenital abnormalities are encountered more frequently in the white than in the negro patient, whereas other lesions except cicatricial stricture of the esophagus which usually results from swallowing a solution of lye occur with equal frequency in the negro and in the white person in accordance with the density of population.

Recent studies have suggested that congenital deformities which occur more frequently in white than in negro people may be related to the Rh factor as this factor is universally present in the latter race. This factor may be the reason for the interesting difference in the occurrence of certain esophageal lesions in the negro and in white persons which is difficult to explain otherwise.

BENJAMIN GOLDMAN M D

Smithers, D W: Short Esophagus (Thoracic Stomach) and Its Association with Peptic Ulceration and Cancer. *Brit J Radiol* 1945 18: 199.

The increase in the number of cases reported as congenitally short esophagus has followed the recognition of the association between this condition and peptic ulceration of the esophagus. Two main and conflicting theories have been put forward to account for the frequent association of partial thoracic stomach with peptic ulceration of the lower end of the esophagus. One theory suggests that a congenitally short esophagus is comparatively common and by causing relaxation of the cardia and a reflex flow of gastric juice leads to peptic ulceration. The other

suggests that peptic ulceration of the esophagus is the primary condition and that scarring and contraction resulting from healing pulls part of the stomach into the thorax. One theory puts a congenital defect first and the ulcer second while the other theory puts the ulcer first and an acquired defect second.

The following theory is offered by the author in an attempt to account for the relationship between partial thoracic stomach with the roentgenological appearance of shortening of the esophagus and peptic ulceration of the esophagus.

1. Congenitally short esophagus is rare being seldom found at autopsy. Many cases so diagnosed during life have an acquired or an apparent shortening rarely demonstrable after death. It results from hiatus insufficiency, sometimes developmental, but more often acquired in later life.

2. When the cardiac sphincter in the thorax is released from diaphragmatic control, gastric juice tends to flow into the esophagus and predisposes to peptic ulceration.

3. Irritation of the esophageal mucosa by gastric juice (or probably by esophagitis from any cause) may produce irregular spasmodic contraction of the

lower end of the esophagus which frequently occurs from side to side, but is a longitudinal contraction or shortening. In cases with an esophagus of normal length the relaxation of the contraction and equalization of the pressure in the thorax and abdomen returns the herniated portion of the stomach to the abdomen by the time that a postmortem examination is performed.

4. Heterotopic gastric mucosa may secrete gastric juice into the esophagus or the gastric contents may reach it in other ways (for example, as the result of vomiting, rumination, or relaxation of the cardia following operations) in patients without a lax hiatus. Peptic ulceration of the esophagus may occur in these patients without roentgenological evidence of shortening of the esophagus.

This theory (first, hiatus insufficiency congenital or acquired, and second spasmodic shortening of the esophagus and ulcer) accounts for the known facts and overcomes the chief difficulties associated with the congenital short esophagus and "fibrosis and contraction" theories.

Two cases of short esophagus and cancer are added by the author to those previously published.

JOSEPH E. NARAT, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Coles, J. S.: Operative Cure of Inguinal Hernia in Infancy and Childhood. *Am J Surg* 1945 69: 166.

In considering inguinal hernias in the young one deals principally with indirect hernias since direct hernias are rare and constitute less than 1 per cent of this group. In order to consider adequate surgical treatment one must be acquainted with the embryological development of a preformed indirect sac. The processus vaginalis, an evagination of peritoneum appears at the site of the future internal ring at the third month of fetal life and soon emerges through the anterior abdominal wall. From the fourth to seventh month, it enlarges while the testis lies in the iliac fossa near the anterior abdominal wall close to the pelvic brim. From the seventh to the ninth month, the testis descends through the inguinal canal into the scrotum behind the advancing processus. The testis after entering the scrotum becomes incompletely enfolded by the processus but the tunica vaginalis, that portion of the processus lying in contact with the testis, has a cavity directly continuous with the peritoneal cavity. It is believed that this sac remains patent in from 30 to 50 per cent of the infants at birth. Normally this processus becomes obliterated from the internal ring to a short distance above the testis. The obliteration is aided by the pressure of the abdominal wall and there is solidification of the processus to form the funicular ligament.

There are several possibilities if obliteration does not occur completely. (1) If the processus and tunica remain open the abdominal contents may enter and form a hernia to the lower pole of the testis the so-called congenital hernia. (2) If the processus closes from just above the testis to a short distance below the internal ring the abdominal contents may enter and form an acquired hernia.

and (3) if the processus narrows but does not obliterate at one or more points from just above the testis to a short distance below the internal ring a hydrocele of the tunica vaginalis or the cord with or without an apparent hernia may develop the so-called congenital hydrocele.

If the abdominal contents fail to enter the open processus in any of these types the processus will gradually be obliterated in many cases. The inguinal canal is so constructed that if there is no patent processus vaginalis it is impossible to produce an indirect hernia regardless of the force exerted. In infants the internal inguinal ring is posterior to the external, the thickness of the abdominal wall being the length of the canal. With growth the internal ring is curved upward and outward which makes the canal longer and more oblique. This results in an increasing resistance over the inguinal canal with straining.

That the indirect inguinal hernia is of congenital origin is emphasized by (1) the fact that the vas and blood vessels of the cord have a uniform relationship to the sac, and (2) the fact that indirect inguinal hernia is more frequent on the right side. The later descent of the right testis is apparently related to this factor. The later descent of the right testis is compensated by its final higher position which equalizes the time of obliteration on the two sides. However if the difference in the processus of the two sides were enhanced a greater frequency of right indirect hernias would be expected.

Since 1938 the author believing inguinal hernias are due only to the presence of a preformed sac, has relinquished the common hernial repairs and relies only on a procedure isolating and ligating the neck of the sac. He believes that he observes testicular atrophy by not transplanting the cord with the danger of compression of the cord vessels by not relocating the testis from its bed which causes postoperative swelling of the testis and by not du-

GASTROINTESTINAL TRACT

Hamilton J. B.: Gastric Volvulus and Other Abnormal Rotations of the Stomach. *Am J Surg* 915 54 30

Gastric volvulus is an abnormal rotation of the stomach. Schatzki and Simeone point out that any position change of the stomach must be some form of rotation and this per se is not necessarily volvulus. They cite as examples the high lying stomachs of obese individuals or the upside down appearance of the high stomach commonly associated with eventration of the diaphragm. However, true volvulus may occur in the presence of eventration.

True gastric volvulus is considered to be present when rotation of the stomach reaching or closely approximating 180 degrees is present. This spontaneously reduces itself or is reducible by manipulation. It can reasonably be assumed to be the result of injury. Other abnormal rotations which are not subject to reduction either spontaneously or manually are believed to be variations on a basis of congenital anomalies.

There is a conflicting terminology of classification of gastric volvulus. Singleton says that "gastric volvulus may be defined as an abnormal anterior or posterior rotation of almost all of the stomach about either the coronal or sagittal axis of the body." The stomach is limited in mobility between the gastrophrenic ligaments above and the peritoneum covering the second portion of the duodenum below. According to the length of the gastrophrenic omentum the stomach may be displaced within these limits by extrinsic pressure. Therefore, pressure displacement is very common but true rotation of the stomach is relatively rare and requires unusually long gastrophrenic and gastroduodenal mesenteries to allow its occurrence.

Singleton classes volvulus as

1. Organo-axial rotation of the stomach upward around the long axis of the stomach i.e. the coronal plane.

2. Mesenteroaxial rotation of the stomach from right to left or left to right, about the long axis of the gastrophrenic omentum. This second type is called torsion or twist of the stomach by others namely Becker, Shanks, Kerley and Twining.

In acute gastric volvulus the rotation is so great that the blood supply is disturbed and immediate surgery is indicated. A series of cases is presented with characteristic x-ray findings and interesting clinical pictures. One case was of a torsion type volvulus 6 cases were of the organo-axial type of volvulus 1 case was believed to be of the organo-axial type and 5 cases showed abnormal rotations which were constant and associated with eventration of the diaphragm. Acute gastric volvulus was not present in any of these cases.

In 1 case the excessive degree of twisting was shown by the pattern of the rugal folds and the bulb position. The spontaneous reduction was characteristic of a diagnosis of torsion volvulus. In obese

individuals a somewhat similar picture is presented by normal high-lying stomachs. This is differentiated from a torsion volvulus by the minor twisting of the rugal pattern and the normal bulb position. The difference between a gastric volvulus and a cascade stomach is emphasized.

Relaxed intra-abdominal attachments are believed to have been present in all cases presented. Obesity, trauma, marked weight loss preceding gastric rotation, and increased intra-abdominal pressure associated with obesity and anomalous development are some of the varying factors in the etiology of abnormal gastric rotations. A large redundant or abnormally situated colon was a feature in several cases of true volvulus. Eventration of the left hemidiaphragm was present in 3 cases and a true volvulus was associated with it in 1 case. Herniation of the diaphragm, 1 case due to trauma and 1 in an obese patient, was seen in 2 cases of volvulus. An unusual congenital variation, a thoracic stomach on the right side congenitally herniated through the foramen of Morgagni, was also reported.

Symptoms, while not characteristic, were present in all but 1 case. These were discomfort or pain in the epigastrium. Six patients had nausea and vomiting. Hematemesis and positive results of the benedictine test of the feces were found in 1 case. Only 3 patients had marked weight loss associated with gastric rotation. In several cases of true volvulus there was a history of similar attacks previously with a complete remission of the symptoms between the attacks.

The characteristic findings in various rotations of the stomach are described and illustrated. They are usually best seen in the upright posteroanterior position before the fluoroscopic screen. It is obvious that in cases of true volvulus the finding may be missed unless the patient is examined during an attack. The differential diagnosis between eventration and herniation of the diaphragm is important since in the presence of herniation a repair of the diaphragm may both relieve symptoms and cause the stomach to return to its normal position. In carefully selected cases it is possible that surgery may be helpful in restoring the stomach permanently to a normal position with relief of symptoms.

ROBERT E. BROWNE, M.D.

Orr T. G.: Pancreaticoduodenectomy for Carcinoma of the Ampulla and Ampullary Region. *Surgery* 1945 8 144.

Pancreaticoduodenectomy for carcinoma of the ampulla and ampullary region is discussed by Orr under six different headings. In addition, he has tabulated or listed the 33 additional cases reported in the literature from April 1, 1943 (date of Whipple's report) to November 1, 1944. In this listing he gives the author, the date reported, the age and sex of the patient, the type of operation, and the results.

The first of the six headings considers the diagnosis at operation. This may be most difficult because chronic pancreatitis or benign adenoma may

so closely simulate carcinoma that a diagnosis made by palpation alone may lead to a needlessly serious operation." In selected doubtful cases duodenotomy and biopsy of the papillary area may be indicated, or a biopsy of the lymph nodes or pancreas may be advisable. If the diagnosis is not clear after a biopsy of the papilla, lymph nodes or head of the pancreas, it is wise to plan the operation in two stages and complete the second stage after a positive diagnosis of operable carcinoma is made.

There has been no accurate publication of the final results of pancreaticoduodenectomy and until a careful study has been made, it will be difficult to state with any degree of accuracy what percentage of cures may result or what the average length of life

will be following this operation. It is also difficult at present to compare and draw conclusions from the results obtained by the palliative operation, the transduodenal resection, and the radical operation. But regardless of the lack of knowledge concerning the final results the radical excision of a carcinoma arising in the ampullary region by the Whipple type of operation fulfills the requirements of cancer surgery in general and offers the greatest hope for the greatest number of cures in the future.

3 After reviewing the experimental and some of the clinical reports on restoration of the external pancreatic secretion Orr asks "Is there any good reason why the end of the divided pancreas should not be united with the intestinal tract?" Then he

answers. Until this question can be answered an unqualified opinion concerning the advisability of restoration of the external pancreatic secretion following pancreaticoduodenectomy cannot be given. However one can state with assurance that it is a physiological procedure to restore the external pancreatic secretion of the intestinal tract.

4 The one-stage operation is preferable if the general condition of the patient will tolerate such an extensive and prolonged procedure with reasonable safety. The earlier that patients with perampullary carcinoma come to operation after the onset of symptoms the greater the number that will be suitable for the one-stage operation. There will be a relatively large percentage of deeply jaundiced and generally debilitated patients for whom the two-stage operation must be chosen. The first stage of the planned two-stage operation has a sufficiently high mortality to warn the surgeon that the choice of operation must be very carefully made.

5 The choice of technique should be guided by the fact that (1) sufficient tissue should be removed about the tumor to include any local infiltration of the tumor and the regional lymph nodes (2) the common duct should be used for anastomosis whenever possible instead of the gall bladder (this will facilitate drainage of the bile and prevent leakage of the bile from the ligated common duct) (3) the anastomoses between the gall tract and pancreas and the jejunum should be made proximal to the gastrojejunostomy to prevent infection of the gall tract and pancreas and (4) anastomosis of the pancreas to the jejunum should be made to prevent pancreatic fistula and to restore the external pancreatic secretion to the intestinal tract. These principles are incorporated in the operation of Whipple Poth, and Child.

6 The author has had 18 cases under personal observation. A study of these brought up the question of the possible operability and curability of such patients. To estimate the value of any operative treatment it is reasonable to include all patients having the disease. Of the first group of 9 patients 2 died following the first stage of the operation, and 1 died on the operating table at the beginning of the second stage. Two patients had palliative cholecystogastrostomies because of extensive metastases. A clinical diagnosis only was made in 3 cases. In only 1 of these was surgery recommended. Of the 18 patients 11 had proved metastases or clinical evidence of metastases. The frequency of metastases in this small number of cases makes one wonder just what percentage of such patients is curable by successful pancreaticoduodenectomy.

SURGEON J. FOGELSON, M.D.

Brandberg, R.: Obstruction following Gastric Resection and Gastroenterostomy. *Acta Chir Scand* 94: 93-97, 37.

Difficulty in emptying the stomach contents into the intestine occurs quite frequently after gastric resection and gastroenterostomy but, generally

recovery is spontaneous without any radical treatment. These temporary obstructions are due to gastroenteric atony. Other causes of obstruction are mechanical or due to distention peritons caused by the operation.

In resection by the Billroth I method, serious obstruction may be caused by distention of the stomach wall at the site of the suturing of the resected surfaces. Therefore this type of resection should be used in only a limited number of cases. The common cause of obstruction in antecolic loop gastroenterostomy with or without resection, is that too short a loop has been used for the gastroenterostomy and as a result the afferent loop becomes too much distended and, therefore, parietic. The stomach empties into this parietic loop while there is little or no emptying into the efferent loop. The loop in this type of gastroenterostomy should be at least 50 cm. long. The same cause may lead to obstruction in posterior short-loop gastroenterostomy with or without resection, but the commonest cause of obstruction in this type of operation is abnormal shortness, fibrous thickening, or high fat content of the mesocolon. This causes so much pressure on the gastroenterostomy loop that it cannot be overcome by the comparatively slight motility of the loop. If there has been a large resection the mesocolon may be pulled up so much that it compresses the gastroenterostomy loop and results in obstruction. All these changes cause distention and paresis of the afferent loop with the result that the stomach empties into the afferent instead of the efferent loop. Therefore, posterior gastroenterostomy should not be used unless the mesocolon is completely normal. If it shows any abnormality anterior gastroenterostomy should be performed. Severe obstruction can almost always be prevented by choosing the right type of gastroenterostomy.

If obstruction occurs after a few days of satisfactory emptying it is apt to be caused by inflammation or adhesions around the gastroenterostomy opening.

Temporary obstructions may be relieved by repeated washing of the stomach or permanent suction, associated with the parenteral administration of sodium chloride and glucose solutions, and in some cases the transfusion of blood. In severe and long-continued obstructions caused by distention peritons with changes in the mesocolon and the formation of adhesions a jejunostomy must be performed for the purpose of feeding the patient. In the majority of cases the obstruction is overcome spontaneously and it is not necessary to perform any of the operations for abolishing it. These operations are often complicated and show a high mortality.

AUDERT G. MORGAN, M.D.

Ten Kate J. The Technique of the Billroth I-Schoemaker Gastrostomy. *Acta Chir Scand* 94: 90-93.

Billroth performed the first successful resection of the stomach for cancer in 1881. In his first method,

called the Billroth I the duodenum was anastomosed to the stump of the stomach at the greater curvature, the part at the lesser curvature being closed. It was soon found that this method involved serious risks because of tension on the sutures particularly at the "fatal suture angle" where three sutures met. Billroth himself gave it up for his second method the Billroth II but Schoemaker modified the Billroth I method so as to free it of its greatest danger. He introduced a curviform incision of the stomach. The antrum is resected together with the greater part of the lesser curvature and the beginning of the duodenum; a tube is formed from the part of the stomach lying near the greater curvature. This is a radical method and yet it economizes normal gastric tissue. The gastric tube is long enough to be united to the duodenum without any tension. A special clamp to be used in the performance of the operation was devised. This clamp and the various steps of the method of operation are illustrated in the original article.

The author believes that with the Schoemaker modification the Billroth I method is possible in any gastrectomy. In penetrating duodenal ulcer with an infiltrated wall, the Billroth II method or a gastroenterostomy is preferable on account of the danger of recurrence. Modern surgical methods are determined more by physiological than by anatomical considerations and the author believes that Billroth himself would now use his first method of operation in preference to his second one.

ANNEX G MORRIS M.D.

Sanders, R. L.: A Review of 161 Subtotal Gastric Resections for Benign Ulcer. *Surgery* 1945 18 320

The 161 subtotal resections upon which this study is based were performed during the past 11 years from 1933 to 1944. There were 13 patients with gastric, or duodenal and gastric ulcers, 11 of whom were operated on from nine months to nine years ago. Ten, or 90 per cent, obtained a good functional result and were free from their former ulcer symptoms. The eleventh patient died of pulmonary embolism on the third postoperative day.

Of the 80 patients with uncomplicated duodenal ulcer 61 were operated upon primarily and in 19 the resection followed a previous operation for the same condition. Of the 61 with primary resections 1 died, a mortality of 1.7 per cent. This incidentally was the first patient of the series, who was operated upon in 1933. Of the remaining 60 patients 50 were operated upon more than one year ago and 48 of these have been heard from since. 33 reported an excellent result with good stomach function and complete relief of their distress; an additional 10 were materially relieved although they still have some minor disturbances such as mild nausea and vomiting after breakfast or some weakness or stubborn weight loss. These 43 patients thus represent 90 per cent of the results which may be classified as excellent or good. Four patients or approximately 8 per cent have clinical and roentgenographic evi-

dence of a recurrent ulcer at the stoma. Of the 19 who underwent secondary operations 16 came to surgery more than 1 year ago. Three of these have some slight nausea and the others report complete relief with a good functional result.

The remaining 8 cases were instances of gastrojejunal (6) and of colonic fistula complicating gastrojejunal ulcer (2). All of these patients were operated upon more than 1 year ago and 1 of the patients with a colonic fistula died. 6 patients have obtained an excellent result, having no symptoms and 1 patient has only occasional nausea. Therefore there were good results in 87.5 per cent of this group of 8 patients undergoing secondary operations and a total mortality of 3 deaths or approximately 3 per cent for the 101 resections. In view of the nature of the operation and the fact that many patients with these lesions have associated disease which materially increases the risk, these results are certainly commensurate with those of other abdominal procedures of similar magnitude and explain in part the continued and increasing preference for this type of operation in the conditions here reported. The author states that they have had no deaths resulting from the resections in these cases for the past 8½ years.

The author also classifies his patients into groups particularly his patients with primary resection for duodenal ulcer from the standpoint of the pathological condition found at operation and the relief to be expected from the operation. For instance, 17, or 34.7 per cent of the patients who were operated upon more than 1 year ago had a bleeding posterior ulcer (7 of them with an associated anterior ulcer). 13 of the 17 were completely relieved and 4 were partially relieved. Thus the entire 17 or 100 per cent were benefited by the operation. The second group consisted of 6 patients who underwent resection for pyloric obstruction, the usual pathology being a posterior duodenal ulcer of long standing although in 2 of the author's patients again there was present also an anterior ulcer. Five of these 6 patients have remained entirely free of symptoms after resection, but 1 still has some nausea with vomiting of bile at times. In the remaining group are 26 patients who underwent resection for intractable pain here again the causative factor seemed to have been a posterior duodenal ulcer eating its way into the pancreas; however in 16 of these cases an anterior ulcer was present as a complication. Of these 26 patients 15 were completely relieved and 5 partially relieved. 4 continued to have considerable discomfort, 1 developed clinical evidence of a gastrojejunal ulcer and 1 died.

Although this series is small it shows that the author's experience is similar to that of other surgeons in that obstructive ulcers of the duodenum have been found most amenable to cure that resection for bleeding ulcer may be expected to give the next best results and that the prospect of complete relief is somewhat less certain for intractable ulcers.

JOHN W. BERNHARD M.D.

Luna D F., and Arzede, F C.: Healing of Tuberculous Ulcers of the Intestine (Curación de las úlceras tuberculosas del intestino) *Rev As med argen* 945 59 634.

About 19 per cent of tuberculous patients die of intestinal lesions which complicate the pulmonary disease. It is therefore, of great importance to cure the intestinal lesions. They begin as a submucous tubercle which undergoes caseation softens empties into the lumen of the intestine, and leaves an ulcer. They are called simple ulcers if they affect only the submucosa penetrating if they affect the muscular layer and perforating if they reach the subserosa. Naturally the shallower they are the more readily they heal. It has been shown that spontaneous healing does occur. The stages in healing are granulation of the ulcers and epithelization. Sometimes new epithelium is produced in excreta. If muscle has been destroyed it is never regenerated. Even if the ulcers heal, a break in the continuity remains in the muscularis mucosae marking the original extent of the ulcer and a gap in the muscle layer which is filled with connective tissue. Stenosis from contraction of ulcers has been reported but the authors did not see any cases of it in 730 autopsies 450 of which were performed systematically in a search for such lesions. Among these 18 ulcers in the process of healing were found.

A detailed histological description is given of the different stages of healing and illustrated with photographs of the surgical specimens and photomicrographs of the histological findings. The process of healing may be hastened by various treatments such as ultraviolet rays and cod-liver oil and orange juice. Spencer Wells was mistaken in reporting that these ulcers could be healed by exposure to air. He based this statement on a simple exploratory laparotomy in a case of tuberculous ulcers of the intestine after which the ulcers healed.

AUDREY G. MORAGAN M.D.

Kock W. Primary Sarcoma of the Small Intestine (Primäres Duodenalcarcinom) *Id. Zt. f. Chir.* 1943 50 37.

Seventeen sarcomas of the small intestine are reported from the records of the large surgical clinics in Stockholm covering the years 1900 to 1941. Most of these tumors were undiagnosed until uncovered by autopsy or operation. However, in 8 patients a tumor could be determined by palpation or with x-rays.

The first of these preoperatively diagnosed cases was that of a boy of 16 years who had suffered for almost a year of recurring attacks of abdominal pain and distention, dyspepsia and anorexia. Physical examination in this instance disclosed large areas of localized resistance with knobby extensile upward toward the liver.

The second example was that of a soldier of 42 years who had suffered for about 2 years with attacks of colic, constipation and flatulence, and frequent attacks of dysuria. He himself had noted a

knob the size of a goose egg, in the right iliac region, and on physical examination there was palpable a mass the size of 2 fists extending from the symphysis to the navel.

The third patient, a man of 27 years had symptoms which began as attacks of colic and diarrhea with loss of weight. Later there was detectable in the right side of the abdomen a rapidly growing tumor.

The fourth patient a female of 66 years had always been anemic and 4 years previously had had attacks of diarrhea. A year previously she had suffered fever, vomiting, colicky pains, and meteorism. Since then there had been attacks of persistent diarrhea, the patient had become pale and cachectic, and the stools evil smelling. Examination in this instance disclosed a mild anemia, eosinophilia, and an occasional positive Weber reaction. The right hypochondrium looked fuller than the left, and dilated loops of bowel could be palpated. Roentgenological examination in 1930 the first in this series of 8 patients wherein the x-rays were mentioned showed a walnut-sized shadow defect on the border between the rectum and sigmoid. With oral administration of the contrast medium there was disclosed a delayed, obstructed emptying of the small bowel and adhesions between loops of the small intestine.

The fifth clinically diagnosed patient a 51-year old female had suffered acid eructations for many years and for the past few weeks had been unable to tolerate highly seasoned and fatty foods—she had experienced frequent attacks of postprandial vomiting and colicky pains from 4 to 5 hours after eating. She had lost much weight in the last half year. A week previously this patient had noted a plum-sized, painless mass alongside of the navel. Examination disclosed a subfebrile temperature and indication of a defense musculature in the right epigastrium. There was a palpable 1 cm plum-sized mass near the navel which seemed adherent to the linea alba. X-rays revealed organic changes in the cecal pole and in the region of the ileal anastomosis into the cecum. Here the diagnosis was not decisive as between inflammation or tumor but operation confirmed the presence of a tumor which was clinically diagnosed as a sarcoma of the small bowel. In this case as in 3 others of this series the diagnosis was not confirmed by microscopic examination of the operative or postmortem specimens.

The sixth instance was that of a female 59 years of age whose case was previously reported by Bl. G. Nilsson (*Id. Zt. f. Chir.* 1933 73 34 576) and who had suffered vague abdominal pains. The tentative diagnosis of tumor of the small intestine was based solely on the roentgen findings.

The seventh case was that of a 60-year-old widow who had suffered for several years with marked flatulence and colic. During the previous several weeks these symptoms had become worse and a medical clinic had made a tentative diagnosis of appendicitis. Examination disclosed anemias, a slightly distended abdomen, and rectal findings sug-

going a tumor of the adnexae on the right side of the colon (possibly merely scybala). X-ray examination, however, gave the findings of a space limiting process beneath and medial to the cecal pole.

The eighth example was that of a male of 72 years who had suffered weakness and loss of weight for 3 months before the tumor in the right iliac fossa was noted since then he suffered at times of meteorism with abdominal distention. The roentgen examination disclosed an infiltration of the wall of the cecum which was regarded as definitely carcinomatous however the pathologicoanatomic diagnosis was lymphosarcoma.

In the remaining 9 patients in this series of small intestinal sarcomas, the symptoms and findings were not greatly different from those of the 8 clinically diagnosed instances cited and indeed not greatly different from those postulated by the world literature on the subject. However all 17 cases are lumped together by the author in an attempt to secure information on the frequency of primary sarcomas of the small intestine in proportion to other malignancies of this region. For instance during the same period (from 1900 to 1941) there were also brought to operation in the surgical clinics of Stockholm, 23 instances of sarcoma of the stomach and 5 cases of sarcoma of the colon—together with a patient in whom a growth involving both the stomach and the colon was uncovered. As regards the incidence with reference to the different sections of the small intestine itself there were 2 tumors involving the duodenum, 2 involving the jejunum, 3 in the ileum, 3 in the ileocecal region, and 7 reported for the small intestine as a whole. There were no instances reported from the children's departments of the Stockholm hospitals the patients being otherwise fairly well distributed for age.

Histopathological examination was reported in 10 of these 17 patients and the pathologicoanatomical findings revealed were the following: 1 round-cell sarcoma of the large-cell type, 2 round-cell sarcomas of the small-cell type, 1 fibrosarcoma of the giant-cell type, 1 myoma sarcomatodes, 1 sarcoma of the reticulum-cell type, 1 hemangiosarcoma and 3 lymphosarcomas.

The data from this material is included in a table showing the surgical methods employed. These methods varied according to the exigencies of the individual situation encountered and the results of such treatment. The results are not especially encouraging and have apparently not improved greatly during the period covered by this report. The author stresses the importance of preoperative and postoperative irradiation treatment none of these patients however were treated by irradiation method prior to surgical intervention and the postoperative applications are not claimed by the author to have produced any markedly beneficial effects. Except for the roentgenological advances the whole subject appears to have remained about where it was a half century ago.

JOHN W. BRENNAN, M.D.

Arendt, J. The Significance of Cannon's Point in the Normal and Abnormal Functions of the Colon. *Am J Roentg* 1945 54 149

The author has noted that frequently twenty-four hours after the ingestion of barium and sometimes immediately after the expulsion of barium enemas the colonic pattern is divided into two distinct parts so that either the cecum, ascending colon and proximal portion of the transverse colon are widely filled with barium while the distal portion of the colon is contracted (Fig. 1) or vice versa. Occasionally however only a contraction ring was noted in the transverse colon. The site of the change from the wide lumen to the contracted one or the site of the contraction ring was usually to the right of the spine between the proximal and middle thirds of the transverse colon, and never much further distal than the middle third. The constancy of the phenomenon has convinced the author that this point is of great functional significance.

He identifies this point with that of the contraction ring described by Cannon in cats, in 1902 and later in rabbits and in man by Boehm who also observed different functions on the two sides: tonic

Fig. Denarcation of Cannon's point (arrow). Ascending and transverse colon wide up to Cannon's point; transverse and descending colon contracted beginning at this point.

Fig. 2 Schematic drawing of the co-ordinated or at times antagonistic colon innervation.

contraction and antiperistalsis in the proximal part of the colon, and deep segmentation with haustration in the distal part. A diagram by Garry showing the functional division of the colon at Cannon's point as established in animals by the experimental physiologists is reproduced and Case's early roentgen study of colon motility in man is recalled.

The author's contribution is his hypothesis that Cannon's point represents the pivoting point of a change in extrinsic innervation of the colon between the vagus and pelvic nerves on the parasympathetic side and on the sympathetic side between the splanchnic superior and inferior nerves (Fig. 2). The precise point where such change occurs has long been in question although the general distribution in the colon of innervation from the various extrinsic sources is well known. The point of change proposed follows well the colonic division as to the blood supply the proximal neurological unit of the colon being supplied by the superior mesenteric artery and the distal part by the inferior mesenteric artery.

If the nerve impulse in ascendancy is the same type in both neurological divisions of the colon, no

demarcation of the two units can be seen roentgenologically but if they are antagonistic, the division is clearly visible. At Cannon's point peristaltic waves tend to flatten out or reverse themselves, the proximal part of the colon being the relatively quiet portion, while beyond Cannon's point the great driving movements have their origin.

The author finds this concept of functional antagonism clinically significant, in that spastic contraction of the distal unit may be a cause of constipation in the ascending colon, and hence best treated by antispasmodics. It also offers an explanation of the observations of Mony and Vernet that kidney stones are often accompanied by painful spasm of the descending and transverse colon with constipation, because of reflex blocking of the distal neurological colonic unit due to the close association of its innervation and that of the urinary tract. Study of the neurological units of the colon has importance also in the differentiation of, and choice of operative method for the different types of megacolon.

LILLIAN DONALDSON, M.D.

Farkas, J. V. Acute Appendicitis. *Minnesota M.* 945 3 35

Farkas analyzes 665 cases of acute appendicitis admitted to the Surgical Service of the Minneapolis General Hospital over a five year period. All are cases of grossly and microscopically proved diseased appendix vermiformis.

The ages of the patients ranged from two to seventy-six years. There were 354 males (53.2 per cent) and 311 females (46.8 per cent). Despite this inequality in the overall figures there was a greater incidence of the disease in females in the earlier periods of life.

There were two definite seasonal peaks, one in midwinter and one in midsummer.

The duration of symptoms ranged from one and one-half hours to seventeen days according to whether the appendix had not perforated (average 25.6 hours) had perforated (average 49.05 hours) or whether there was a definable mass present (average 6.4 days).

Six hundred and forty-eight patients were treated surgically. Of the remaining 17 patients, 15 had definable masses and the disease apparently was under adequate control, 1 was an eleven-year-old girl who was extremely ill, with a temperature of 104° who expired after three days of hospitalization and the last was a seventy-six year-old man who was admitted to the hospital in a moribund state and expired the same day.

A McBurney incision was done in 524 cases and a rectus muscle approach was used in 140 instances 79 of the patients in this group were females.

The stump of the appendix was inverted in less than half of the cases, and apparently there was no difference postoperatively between those patients in whom this technique was employed and those in whom it was not utilized.

Only in cases with abscess formation were drains used. Sulfonamides given orally or intravenously

were administered postoperatively in full therapeutic doses to patients with evidence of peritonitis.

It is believed that the use of morphine prior to surgery was a helpful aid in interpretation of the true pathological state because of the elimination of muscle spasm.

Spinal anesthesia was the method of choice.

The hospital stay varied with the type of incision. Following the McBurney incision it averaged seven and three tenths days and following the rectus incision, eleven and three tenths days, whereas patients with perforation of the appendix were required to remain for an average of nineteen and four tenths days.

Bacteriological studies when done were not remarkable, the usual intestinal inhabitants (*Escherichia communis*, *Escherichia communior* and non hemolytic streptococci) being found.

There were 13 (1.94 per cent) deaths, 11 (1.65 per cent) of which occurred postoperatively. All of the latter occurred in patients who had had perforated acutely infected appendixes and generalized peritonitis.

Postoperative complications other than urinary retention included pulmonary atelectasis, subphrenic abscess, wound infections, postoperative wound eversion, and 1 large pelvic abscess. There were other complications which were not postoperative such as acute appendicitis complicating pregnancy, acute appendicitis complicating the puerperium, and Meckel's diverticula. There were no deaths among this group of patients.

STEPHEN L. ZISKIN, M.D.

O'Connor, H. A. D. and Beale, E. M. Appendicitis: A Survey of the Last 2,000 Consecutive Cases. *J. Ark. State J. M.* 1945 45: 1535.

The entire series of cases presented is taken from the service of the senior author at the Brooklyn Naval Hospital and constitutes a completely unselected group of 2,000 consecutive patients operated upon for appendicitis from October 1942 to September 1944. The preoperative care, anesthesia, operative technique and postoperative management are described in detail.

The authors believe that in these cases more attention should be paid to the history and less to the physical findings and laboratory reports and that appendectomy should be done on the suspicion of appendicitis rather than on the established diagnosis. They recommend the free exhibition of the sulfonamides in adequate dosage given intraperitoneally with liberal use of the Wangensteen type of gastric drainage and of intravenous fluids and the adoption of an operative technique which make appendectomy relatively safe and simple even for the tyro.

ERIC C. ROSENBERG, M.D.

Ochsner, A. and Johnston, J. H. Appendicitis Peritonitis. *Surgery* 1945 17: 873.

Cases of ruptured appendicitis admitted to the Charity Hospital, New Orleans in 1933 and 1934

were studied and analyzed. These two years a decade apart were chosen because in the former group no sulfonamide drugs were employed, no attention was paid to plasma proteins, and gastrointestinal decompression was inadequately used. The cases were classified in three groups in accordance with the type of complication associated with rupture of the appendix as follows: (1) generalized peritonitis, (2) localized peritonitis, and (3) localized abscess.

The incidence of localized peritonitis was about the same in the two groups, while the incidence of generalized peritonitis decreased and that of localized abscess increased in the 1934 group. A comparison of the treatment and results in the years of 1933 and 1934 indicates that the therapy now employed is more effective than that which was used formerly.

The use of sulfonamides has been a boon in lowering the mortality and the morbidity, but the use of large amounts of blood and plasma, the employment of gastrointestinal decompression, and the use of oxygen have been equally important. The combined mortality rate in all types of appendical peritonitis in the 1933 series was 15 per cent, and in the 1934 series was 5.2 per cent. In 20 patients with localized peritonitis admitted in 1934 there were no deaths in contrast to a mortality rate of 13.4 per cent in the 1933 series. In the patients with generalized peritonitis the mortality rate in the 1933 group was 23.5 per cent, whereas in the 1934 group it was 14.2 per cent. There was no significant variation in the mortality rate for patients with localized abscess in the two series. The lack of improvement in the mortality statistics in cases of localized abscess is probably due to the ineffectuality of the sulfonamide drugs in localized suppurative processes. These statistics demonstrate the necessity of instituting drainage of localized collections of pus before sulfonamide drugs can be effectual.

A plea is made for careful study and individualization in every case of appendical peritonitis. The authors advocate (a) immediate appendectomy in all cases of unruptured appendicitis, (b) immediate appendectomy in all patients with ruptured appendicitis in whom there is not definite and demonstrable localization (thus, they believe in immediate appendectomy in the localized and generalized peritonitis cases of the diffuse type) and (c) conservative therapy in all cases of localized inflammatory processes. This treatment consists essentially of obtaining absolute rest of the gastrointestinal tract by withholding everything by mouth, the liberal use of morphine, the application of external heat to the abdomen, gastrointestinal decompression, the liberal use of blood and plasma to avoid anemia and hypoproteinemia, parenteral administration of sulfonamide drugs, and oxygen to aid in preventing distention. The authors believe that in 75 to 80 per cent of such cases the inflammatory process will quickly recede and that interval appendectomy should be done at a later date. In from 20 to 25 per cent of such cases localized suppuration

will occur and will require drainage. Great care in avoiding uninvolved peritoneum in such drainage is imperative.
 Jon I. Lindquist, M.D.

Wiklander O. Rectal Prolapse in Children. *Acta chir scand.* 945, 92, 7.

Rectal prolapse is much more frequent in children than in adults. Almost 90 per cent of the cases occur in children. The prolapse generally begins during the second year of life and there is a tendency toward spontaneous healing.

The author discusses 48 cases treated from 1932 to 1942. About two-thirds of the cases occurred in boys. Constipation is an important contributory cause having been seen in more than 50 per cent of the cases. However, not enough attention has been paid to poor social and economic conditions in the causation of this condition. The majority of these children came from poor homes in which they had been neglected and in more than half of the cases re-examined, treatment had been inadequate.

Because of the tendency toward spontaneous healing, treatment should at first be conservative. The child is kept in bed, the diet regulated, and complete abdominal pressure is avoided by allowing the child to defecate while lying down or sitting on a vessel with his legs hanging. If conservative methods do not give good results or if there is fear of recurrence from neglect after the child goes home, operation may be used, although conservative treatment should be prolonged for at least a month before surgery is used.

The surgical methods most in use are those of Thiersen and Ekeborn and stripping by diathermy. The results obtained by stripping are as good as those from the other methods, as permanent healing takes place in from 85 to 90 per cent of the cases. Stripping is recommended as the simplest and least dangerous surgical method. The prolapse is pulled forward and after about 6 longitudinal stripes are cauterized they are sutured along the prolapse with a diathermy bulb up to and particularly at the transition to the skin. Then the prolapse is reduced and the child kept in bed for a week on a laxative diet. If only longitudinal stripes are sutured with a distance of a or 3 cm. between them there is no danger of stricture.

Audrey G. Morgan, M.D.

Blalodell, P. C.: Traumatic Injuries of the Rectum. *J Am M Ass.* 945, 28, 559.

Rectal injuries commonly result in perineal complications due to the fact that these wounds tend to become fistulous. The less a lacerated wound approximates a penetrating one, the less likely it is to become a fistula. The primary suturing of traumatic rectal wounds constitutes potentially the most serious violation of principle. It has been proved that healing has been delayed far beyond that of wounds left wide open from the start. Primary suturing may be responsible for fistulas which are totally incurable or an operation necessitating far greater mutilation for cure than if the wound was

left open. Acute abscesses are a frequent intermediary stage between either a closed or a bridged wound and the final chronic fistula. This extension of pus under pressure may expand many times the limits of the original injury. The danger of incontinence by the prolonged separation of muscle ends through continued packing of the wound must be considered.

In injuries to the anal sphincter it is found that when the severed ends are left apart and no effort is made to bring them together, this area must be watched for bridging. It is believed that the traumatically injured sphincter should be left alone to take full advantage of its own capacity for spontaneous recovery.

A colostomy is not a preventive of fistula. Subsequent unsmooth healing is due primarily to faulty wound architecture which is shown by the fact that the recurrence rate is so times greater in sutured than in open wounds. In the treatment of the intermediary abscesses the site of incision itself becomes part of the residual fistula.

Four cases of traumatic injury to the rectum are presented in abstract form, and in 3 cases mismanagement is charged.

RICHARD J. BENNETT, JR., M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Zachos, A.: Uremia in Lesions of the Liver and Bile Ducts. *Acta chir scand.*, 943, 28, 383.

It has long been known that there is decreased diuresis in patients with liver disease. About the middle of the last century attention was called to the fact that in patients who had died from some forms of liver disease there were also lesions of the kidneys which were considered secondary to the liver lesions. Not only retention of water is found, but also increased blood urea, acidosis, and the presence of parenchymatous lesions of the kidneys, although the latter may be slight. Such lesions occur not only in liver disease but also after operations on the bile ducts more frequently than has been believed. In severe cases the patient may die with the clinical picture of uremia.

Thirteen cases of uremia occurring in diseases of the liver and bile ducts are described. Tables and graphs in the original article show the course of the disease. Treatment must be directed toward improvement of the function of the liver and also of the kidneys, particularly toward increased diuresis. Careful examination should be made before any proposed operation on the liver or bile ducts is performed, and if kidney function tests are unsatisfactory operation should not be performed. After operation, shock should be combated by blood transfusion. The patient who has had an extensive operation requires about 3 or 4 liters of water in 24 hours, which should be given him by mouth as soon as he is able to drink. Glucose also should be given after the operation. Excessive use of salt solution

may cause edema even edema of the lungs. If there is acidosis an isotonic sodium bicarbonate solution should be given at once. Intravenous or subcutaneous.

The prognosis is bad. Only 2 of the patients in this series recovered. It is possible that some of the others might have been saved if treatment had been given in time.

ANDREW G. MORGAN, M.D.

Narat, J. K., and Cipolla, A. F.: The Fragmentation and Dissolution of Gall Stones by Chloroform. *Arch Surg* 1945 51: 51.

As a rule, mechanical means are sufficient for the removal of stones from the biliary tract. Therefore the field of usefulness of a chemical solvent is so limited that only two indications can be suggested:

1. When a stone is firmly lodged in the common duct and cannot be removed manually when the surgeon is not certain that all broken particles of the stone have been removed, or if the stone is firmly lodged close to the ampulla of Vater, the use of a solvent may obviate the necessity of opening the duodenum.

2. When a stone in the hepatic duct slips away into the liver in the course of attempts to remove it mechanically.

In such circumstances injections of heated chloroform may be given a trial because this method apparently does not represent a therapeutic hazard. To play safe it is advisable to use not more than 5 or 6 c.c. of the solvent and to pinch the hepatic duct during the procedure. In experiments in vitro as well as on animals the use of heated chloroform proved to be superior to ether as an efficient solvent of gallstones.

Repeated injections of chloroform during the post-operative period should be discouraged because they are not efficient and represent a potential hazard.

S. RUTH KARY, M.D.

Voelz, E. F.: Four Cases of Acute Pancreatitis in Previously Cholecystectomized Patients. Remarks Concerning Recurrences in 46 Cases of Acute Pancreatitis (Vier Fälle von akuter Pancreatitis bei vorher cholecystektomierten Patienten. Einiges ueber Rezidive in einem Material von 46 akuten Pancreatitis-fällen). *Acta chir scand* 1943 85: 250.

At the time when radical treatment of pancreatitis was popular it was customary to remove the gall bladder in the course of the operation because gall stones undoubtedly represent the most frequent cause of pancreatitis. Cholecystectomy had the purpose of speeding up the recovery and preventing recurrences. Removal of the gall bladder was also advised in each case of cholelithiasis to prevent the development of pancreatitis. However numerous observations showed that the expected results were not always achieved.

The author reports 4 cases of acute pancreatitis in patients in whom the gall bladder had been removed from 1½ to 4 years previously. He also reports 46 cases of acute pancreatitis. The material is divided into two groups: cases treated in a conservative manner and cases treated by cholecystectomy. In the last mentioned group the operation was performed on 4 patients during an acute attack and on 3 patients during the interval. Two patients who were operated on during the attack developed recurrences. In 23 patients treated in a conservative manner the condition became chronic and in 7 it recurred. The author concludes that no great difference existed between both groups as far as development of chronicity or recurrences was concerned.

The author realizes that his material is too small to allow any definite conclusions, but nevertheless he is inclined to believe that cholecystectomy has no great prophylactic value in the prevention of acute pancreatitis.

JOSEPH K. NARAT, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Zondek, B. Sulman F. and Black, R.: *Hormone Pregnancy Test J Am M 12 1945 1: 950*

In an effort to determine a more rapid pregnancy test the authors have worked with infantile female rats from three to five weeks old and weighing from 20 to 25 gm. They have discovered that the hyperemia hormone pregnancy test is 100 per cent accurate in a twenty-four hour reading for the determination of pregnancy, but it is not as yet sufficient for the diagnosis of disturbed pregnancy which includes ruptured extrauterine pregnancy and threatened incomplete and missed abortion. There may be a 1 per cent error due to tumors in nonpregnant individuals. The two- and six-hour tests can be relied on if the results are positive.

The hormone pregnancy test is based on the following gonadotropic reactions of the ovary in infantile rodents: anterior pituitary reaction I (follicle ripening and induction of vaginal estrus) anterior pituitary reaction II (hyperemia of the ovary and follicle hemorrhage) anterior pituitary reaction III (the formation of corpora lutea).

In developing the pregnancy test it was found that only anterior pituitary reactions II and III may be used for an accurate evaluation of the test despite the presence of large amounts of the lutealizing hormone indicates pregnancy. Infantile mice were first used because of the ease of finding the blood dot, but this method takes four days. Friedman next used rabbit, but this requires well organized breeding, separation of the rabbits for four weeks and in the subtropical climate of Egypt false positives were obtained. If the blood dot is to be used as the indicator for gonadotropins, the mouse or rabbit is most suitable, whereas if hyperemia is to be used the rat is most fitting.

The authors designated a hyperemia unit as the amount of gonadotropic hormone which induces hyperemia of the whole ovary in an infantile rat within twenty-four hours. Hyperemia is evoked mainly by luteinizing hormone and follicle stimulating hormone has only an augmentative effect. For the exact diagnosis of pregnancy the right dosage is important since the injection exceeds a certain amount.

Urine results in positive reactions in nonpregnant women with functional disturbances. The most practical dose was found to be 4 c.c. in two subcutaneous injections of 2 c.c. in an interval of one hour. If the reaction is positive, the ovaries appear slightly brighter than the spleen, a saline, pearl-strawberry red. This test can also be used for the diagnosis of hydatidiform mole and chorionepithelioma. In the latter a gray vesicle is obtained with 0.0003 c.c. of urine.

The investigators have found therefore that the hyperemia test is sufficient when it is a question of

the simple determination of pregnancy. If there is a suspicion of disturbed pregnancy, such as bleeding of uncertain cause, the ordinary hormone pregnancy test cannot be dispensed with. Then at present developing the follicle-stimulating hormone (FSH) test in the rat so that in the future the rat test may also be used in cases of disturbed pregnancy.

CASE 31 BY B. J. S. M.D.

Siegler, S. L.: *An Evaluation of Ectopic Pregnancy with Selective Data from 327 Consecutive Cases. J Ark State J M 1945 45: 194*

The author evaluates 127 consecutive cases of ectopic pregnancy during a period of 15 years at the Units Hospital, Brooklyn, New York. There was an incidence of 2.3 per cent ectopic pregnancy in gynecologic admissions. 8.1 per 1,000 pregnancies or an incidence of 1 ectopic pregnancy to 123.4 pregnancies occurred.

In 24.5 per cent of the patients the ectopic pregnancy occurred as the first pregnancy. 33.0 per cent had had 1 preceding pregnancy. 26.8 per cent had had 2 previous pregnancies and 14.8 per cent of the patients had had from 3 to 6 previous pregnancies. Repeated abortions increased greatly the incidence of ectopic pregnancy. A relatively sterile period of 5 years or more preceded the abnormal pregnancy in more than two-thirds of the cases.

The author states that the etiology probably varies greatly. It may be ovular disturbance, implantation, or mechanical. The residual of pelvic inflammation, disease, appendicitis and other previous operations were factors in 78 per cent of the cases. Three cases occurred following tubal insufflation following tubal occlusion.

The symptomatology was variable, especially with regard to the type of pain which was sharp and stabbing, or dull and colicky. In 89 per cent of the patients the first complaint was pain. Atypical vaginal bleeding was seen in 87 per cent of the patients and consisted of menses occurring at the normal time but prolonged, menses at the normal time but diminished, menses delayed several days or weeks and those patients in whom there was no bleeding until the onset of their symptoms. Twenty-four per cent of patients had nausea and vomiting.

The physical findings showed abdominal tenderness in 90 per cent of cases, a tender cervix and palpable adnexal masses were found in 92 per cent of patients.

History and physical findings in the diagnosis. The biologic test was done 5 times and was of doubtful value in the nonpregnant case for differential diagnosis.

The author believes that curettage has a select but limited value in diagnosis. The microscopic finding of decidual reaction is not a positive indication of ectopic gestation and conversely it does not

does not give proof of its presence. The finding of chorionic villi gives evidence of an intrauterine pregnancy. In 3 cases in which Friedman test was positive the curettings showed proliferative endometrium in 1 case hyperplastic endometrium in 1 case and decidual reaction in 1 case.

At operation 48 per cent of cases were found to be ruptured tubal pregnancies 35 per cent were tubal abortions and 13 per cent were unruptured tubal pregnancies. In 48 per cent of the cases the condition occurred on the right side and in 45 per cent on the left side. The appendix was removed in 36 cases with 2 resultant deaths. General anesthesia was the anesthetic of choice.

The author believes that a large number of patients can be saved before a state of irreversible shock sets in by prompt and massive transfusions of blood plasma or whole blood.

There were 5 deaths with a surgical mortality of 3.1 per cent. CATHERINE B. HESS, M.D.

Bowles, H. E.: Cervical Pregnancy. *West J Surg* 1945 53 226

Cervical pregnancy is extremely rare. The author presents a review of all of the cases in the literature (54) with the available data in each case. The one argument in the diagnosis of each case is as to whether it is a cervical abortion or a true cervical nidation.

The etiological factors are discussed. Retention of a previously detached ovum is favored by a stenosis of the outermost portion of the cervix. The pathological evidence of a true cervical implantation is also reviewed.

Cervical pregnancy is a formidable condition accompanied by a high maternal death rate and also a high fetal death rate when the fetus develops to the stage of viability. The diagnosis is based upon painless and copious bleeding in the presence of a markedly ballooned-out lower uterine segment.

The treatment of this condition depends on the stage at which it is first diagnosed. Emphasis is placed on extreme gentleness as the cervix is often paper thin and may tear extensively with even moderate roughness. Every form of supportive treatment must be available.

In early cases enucleation with a gloved finger or with placental forceps has been suggested. In several cases ligation of the lower branches of the uterine vessels was done to control the profuse bleeding. Vaginal hysterectomy may be done if necessary to control the bleeding if this is not possible abdominal hysterectomy may be resorted to. The cervix should be removed but if this seems inadvisable a supravaginal hysterectomy and firm packing of the cervix may suffice. In late pregnancy abdominal caesarean section seems the logical means of approach, with the liberal use of sulfonamides and penicillin.

The author reports a case of cervical pregnancy at 4½ months gestation treated by supravaginal hysterectomy with recovery. HARRY FIELD, M.D.

Andros, G. J.: The Blood Pressure in Normal Pregnancy. *Am J Obst* 1945 50 300

In the study of 300 cases of normal pregnancy followed through three trimesters it has been found that the systolic blood pressure does not vary significantly during any period of gestation, nor does it deviate from what might be considered normal systolic blood pressure for healthy nonpregnant women.

There is evidence that diastolic blood pressure tends to be slightly lower in the first and second trimesters of normal pregnancy than in the normal nonpregnant state.

On the basis of this study it would appear that any persistent even though slight increase in either systolic or diastolic pressure during pregnancy should be looked upon as potentially significant.

EDWARD L. CORNWELL, M.D.

Wilson, J. R.: Carcinoma of the Cervix Complicated by Pregnancy. *Am J Obst* 1945 50 275

Since 1931 6 patients with carcinoma of the cervix, complicated by pregnancy, have been treated at the Chicago Lying in Hospital. Of these 2 were referred to the hospital for treatment after the diagnosis had been made elsewhere. During this same period a total of 39,719 patients have been delivered thus the incidence of cervical carcinoma is 1 in each 6,600 deliveries or 0.015 per cent. All of the lesions were of squamous-cell origin with the exception of 1 which was an adenocarcinoma.

The existence of pregnancy and carcinoma of the cervix together is unusual and presents a difficult problem in therapy but an unusual opportunity to treat early lesions may present itself. The prompt and thorough investigation of bleeding during pregnancy is an important step in diagnosing the condition and may be responsible for saving the life of the patient. In most instances radical surgical procedures have no place in treatment since the results from combined irradiation are equally as good. A high fetal mortality is inevitable since it is usually unwise to resort to methods of treatment which attempt to preserve the fetus but which may decrease the chances for cure of the neoplasm.

Of the 3 patients in this series who were eligible for consideration 2 (67 per cent) survived longer than 5 years after treatment only 1 however is free from evidence of carcinoma.

EDWARD L. CORNWELL, M.D.

LABOR AND ITS COMPLICATIONS

Johnson, H. W.: The Conservative Management of Some Varieties of Placenta Previa. *Am J Obst* 1945 50 348.

It is suggested that obstetric textbooks be revised as regards maternal prognosis in placenta previa. The author has seen no maternal death from placenta previa where nature has been allowed to take its course as regards labor and delivery. He believes that all cases of vaginal bleeding in the last trimester

There was only 1 gross infection in the entire series and 1 complete breakdown. The latter occurred in a median perineotomy wound with third-degree extension which became grossly infected subsequent to the employment of local anesthesia.

EDWARD L. CORNELL, M.D.

NEWBORN

Schmitz, H. E., and Babo, G.: Aquinone during Labor: Its Effect on the Prothrombin Level of the Newborn Infant. *Am J Obst* 1945 50 20

A total of 23 unselected cases of newborn infants was investigated. They were classified according to whether the laboring mother had received no medication, some form of analgesia (usually cycloal sodium), both analgesia and aquinone or only aquinone. The percentage of cases which remained above the 75 per cent minimum prothrombin level was as follows: no medication 63 per cent, analgesia alone 50 per cent, both analgesia and aquinone 84 per cent, aquinone alone 90 per cent. Even more significant was the percentage of cases falling below the 70 per cent level, since many clinicians consider values below this level to be an indication for vitamin K therapy (in diseases accompanied by prothrombinemia) and values below 40 per cent as lethal in the danger zone. In cases in which no aquinone was used the percentages were 30 per cent and 41 per cent for the no medication group and the analgesic only group respectively, while in cases in which the aquinone was used the percentages were 8 and 0 for the 'aquinone-analgesic' group and the aquinone alone group respectively.

In this small series of cases no definite conclusion could be drawn nevertheless certain incidental observations are set forth. Icterus of varying degree was frequently seen in spite of the high normal prothrombin level (over 92 per cent). In some cases the icterus was quite marked in spite of the normal clotting time. On the other hand, other cases with a prothrombin level below 40 per cent manifested no icterus. (See also L. CORNELL, M.D.)

Linn, K. T. and Snyder, F. F.: The Effect of Respiratory Stimulants in the Newborn Infant. *Am J Obst* 1945 50 40

In newborn rabbit significant stimulation (respiration was difficult to demonstrate) following alpha lobeline, coramine or caffeine and following metrazol or cyanide the slight stimulation was transient and lasted less than a minute.

A considerable hazard involved in the use of these drugs was found to be the narrow range between the dosage which affected respiration and that which caused convulsions. Two or three times the effective dose usually resulted in convulsions in animals which had received pentobarbital premedication.

Injury resulting in death frequently followed convulsions which occurred after alpha lobeline, coramine, and caffeine. Survival occurred after metrazol and cyanide despite the occurrence of convulsions.

The present experiments lend no support to the use of alpha lobeline, coramine, caffeine, metrazol or cyanide in the resuscitation of the newborn infant.

EDWARD L. CORNELL, M.D.

Morison, J. E.: Thrombosis of the Aorta in the Newborn: 3 Cases, 1 with Infarction of the Liver. *J Path Bact Lond* 1945 57 221

Aortic occlusion is extremely rare and it is often difficult to say whether it is due to embolism or thrombosis. The author presents 3 cases and calls attention to the postmortem findings.

The first infant died on the eighteenth day of life from uncertain cause. The anatomical diagnosis was focal arteritis of the abdominal aorta (thrombosis of the aorta extending into the celiac artery), thrombosis of the left renal and inferior mesenteric arteries, infarction of the liver and left kidney, patchy hemorrhagic infarction and ulceration of the stomach and descending and pelvic colon, a pirated amniotic fluid with fibrin reaction in the alveoli, diffuse atelectasis, small subarachnoid hemorrhages with localized thrombosis of the related meningeal vessels, balanitis and left subacute otitis media.

The second infant died on the fifth day of life with otitis media and severe diarrhea. The anatomical diagnosis was congenital aneurysm of the ductus arteriosus communicating with the aorta and mortem thrombus in the thoracic aorta, non-specific pharyngitis and laryngitis with ulceration, terminal pneumonia, acute bilateral otitis media and acute non-specific esophagitis.

The third infant died on the ninth day with jaundice and diarrhea. The anatomical diagnosis included thrush and a associated bacterial infection of the upper respiratory tract, a periton bronchopneumonia, bilateral renal venous thrombosis, red and white venous infarcts in both kidneys, organizing melotic thrombus in the pulmonary arteries and terminal thrombosis of the renal arteries and abdominal aorta.

In the first patient the thrombosis was associated with a peculiar arteritis; in the other cases it appeared to be secondary to other lesions.

JAMES F. DOUGHERTY, M.D.

Potter, E. L.: The Effect on Infant Mortality of Vitamin K Administered during Labor. *Am J Obst* 1945 50 215

Evidence has been produced (1) many investigations in which there is no doubt that in the majority of infants the prothrombin time is prolonged during the greater part of the first week of life, beyond that which is normal for the adult; (2) that the administration of vitamin K to the mother prior to delivery with infant after birth will usually prevent the continued prolongation; (3) that after prolonged treatment in the neonate or infant administration of vitamin K will also cause a return to normal.

There is no proof, however, that prolongation of prothrombin time is a direct cause of hemorrhage. Many infants with excessively prolonged prothrombin

bin time show no evidence of hemorrhage while others with relatively little prolongation bleed severely. Since almost all infants show some prolongation of prothrombin time during the first week, all who bleed from any cause would be expected to show some abnormality.

The optimistic prophecies which were made early in the study of vitamin K in regard to the prevention of hemorrhage and the reduction in mortality rates following routine administration of vitamin K do not seem to have materialized. The present study as well as the investigations of Sanford *et al* and Parks and Sweet, indicate that in a carefully studied group of infants anything which can be considered hemorrhagic disease is extremely rare and that the incidence of the hemorrhages which do occur in this age group is not modified by administration of vitamin K to the mother prior to delivery or to the infant after birth.

In the present study which was carried on for a period of almost 4 years 6,560 infants weighing over 1,000 gm. were born during the two years in which vitamin K was given, and 6,630 were born during the next 22 months. The total fetal and infant mortality rate of 29.8 for the first 2 years is higher than that of 25.8 for the last 2 years in spite of the fact that no change of significance occurred in the incidence of primiparity, premature delivery, mode of delivery, or other known factors. The mortality rates for liveborn infants are identical in the two series as are also the numbers of infants who showed evidence of hemorrhage on postmortem examination.

The conclusion was that no decrease in infant or fetal mortality can be expected to result from the routine administration of vitamin K to all women during labor.

EDWARD L. CORNELL, M.D.

MISCELLANEOUS

Baird, D. The Influence of Social and Economic Factors on Stillbirths and Neonatal Deaths. *J. Obst. Gyn. B. & Empire*, 1945 52: 217.

In order to compare stillbirth and neonatal mortality rates in different social classes, the records of 3 groups of Aberdeen cases have been analyzed. Group 1 was a series of 1,419 delivered in a nursing home, belonging to the Registrar General's social classes 1 and 2 and mostly under the care of the family doctor. Group 2 was a series of 8,808 booked hospital cases, under the care of specialists belonging to social classes 3, 4, and 5. Group 3 consisted of 501 cases in private specialist practice. In the 3 groups the stillbirth rates were 25.3, 30.4, and 10.0 per cent respectively and the neonatal mortality rates 13.0, 34.5, and 8.1 per cent.

In Groups 1 and 2 the stillbirth rates in full time and premature infants were the same and in each group the stillbirth rate in premature infants was 20 times that in full time infants. The excess mortality of Group 2 over Group 1 was due to the incidence of prematurity in Group 2 being almost double that in Group 1.

The patients in Groups 1 and 3 were in the same social class and the differences in the stillbirth and neonatal mortality rates were probably due to different standards of obstetric care. In Group 1 the stillbirth rate fell from 47.6 per cent in the years 1933 to 37 to 14.9 per cent in the year 1944. This fall was due mainly to improved obstetrics.

In Group 2 the stillbirth rate was 3 times that in Group 3, although the standard of obstetrics was the same. There was very little scope for reduction in the stillbirth rate in Group 2 except by measures designed to improve the health of the mother.

The problem of the high neonatal mortality in Group 2 is largely one of the prevention of prematurity. Seventy per cent of the deaths in premature infants occurred within 48 hours of birth, most of the infants being too feeble to maintain a separate existence.

The stillbirth rate is relatively high with first pregnancies least in the second and thereafter rises with each pregnancy. The rate rises with age in each parity. In Group 2 primiparas the stillbirth rate in the age group from 25 to 34 was nearly 5 times that in the same age group of Group 1 primiparas.

The reproductive efficiency in Group 2 as measured by the stillbirth rate fell off steadily after the age of 30, whereas in Groups 1 and 3 the fall in efficiency was delayed till the age of 30.

In Group 2 63 per cent of the primiparas were under 25 years of age and in Groups 1 and 3 19 per cent. The stillbirth rate in the latter groups would be very high if the reproductive efficiency in these groups fell off as quickly with age as it does in Group 2.

Over 30 per cent of the stillbirths in full time infants in Group 2 are due to intrauterine death of the fetus from unexplained causes. The cause of the onset of premature labor is unexplained in about 50 per cent of the cases in this group. The most probable explanation in both cases is poor health and nutrition of the mother.

From a national point of view the stillbirth and neonatal mortality rates will be most substantially improved by improvement in the standard of health and nutrition of the mothers in Social Classes 3, 4, and 5 corresponding to Group 2 in this series as they constitute the vast majority.

DANIEL G. MORTON, M.D.

Falk, H. C. and Blinick, G. The Pathogenesis of Postabortal Peritonitis. *Am. J. Obst.*, 1945 50: 168.

In this series of 61 cases of postabortal peritonitis all patients presented an endometritis of varying severity. The infection spread from the endometrium to the peritoneum as a result of direct extension through (1) the tubes, (2) the parametrium, (3) the myometrium, and (4) by a combination of these routes.

Direct extension through the tubes seemed to be the pathway of infection in 40, or 66 per cent, of the cases studied.

Extension of the infection from a parametritis to the peritoneum occurred in 6 or 10 per cent of the patients. In 1 patient the peritonitis was caused by rupture of a broad ligament abscess into the peritoneal cavity.

The infection extended through the myometrium in 4 or 7 per cent of the cases.

In 6 patients endometritis salpingitis parametritis and peritonitis were present. The pathway of infection was not clear.

In 4 patients endometritis abscess of the myometrium, salpingitis and peritonitis occurred. It is probable that in this group the tubes were the chief pathways of extension as the myometrium contained discrete abscesses with no contiguous inflammation of the enveloping peritoneum. The cases are not included in the first group because of the questionable etiology of the peritonitis.

Ovarian abscess was found 17 times, an incidence of 18 per cent. Thrombophlebitis of the uterine or ovarian veins or of both occurred in 10 or 33 per cent of all the patients observed. It was more common in the patients with parametritis or myometritis alone or in combination, than in those with salpingitis alone. Of 40 patients with salpingitis and peritonitis 10 showed phlebitis whereas in the 20 cases with parametritis myometritis and peritonitis 10 showed venous inflammation. In 5 of the 20 patients there was localized thrombophlebitis. In 5 embolic abscesses of the lungs were present. No other sites of embolization were found despite careful study.

In this series the most common pathway of infection to the peritoneum was by direct extension through the tubes. EDWARD L. CHANCELL, M.D.

Thoma, C. and Hagaman, J. B.: The Acceptability and Effectiveness of the Condom As a Contraceptive Method. *Am. J. M. Sc.* 1945, 10: 189.

The authors present the condom as an acceptable and effective means of contraception from a public health point of view. A study was conducted under the auspices of the National Committee of Maternal Health, in Watauga County, North Carolina, a rural area with little education as far as birth-control methods were concerned. Condoms of high quality were used. Mostly white people of the farmer class were used in the author's study.

The need for birth control was discussed with all wives concerned in the study and the use of the condom explained. A total of 658 married couples were included in this study and their experiences were followed from September, 1939 to late in 1943. Contraceptive techniques (including withdrawal) had been used by 45% of all couples and were being used at the time of the interview by 38 per cent. Of the 140 couples practicing contraception, 65 per cent were using condoms, 7 per cent withdrawal, 3 per cent douches with jellies, suppositories, safe period and diaphragm each accounting for 1 per cent or less.

Supplies were accepted and used by 39 per cent of the couples. Of these 73 per cent were still using them after a period of 36 months. The degree of protection offered by means of contraception approximated that reported for the diaphragm and jelly and exceeded that afforded by foam powder and by jelly alone.

The prescription of condoms for the prevention of dangerous or undesirable pregnancies requires little of the physician's time and is well suited to inclusion in public health programs. HARRY FIELDS, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Dahl Iversen E: The Technique of Suprarenalec-
tomy and the Use of This Operation for the
Genitoadrenal Syndrome in Childhood (Tech-
nique de la surrénaléctomie et surrénaléctomie pour
le syndrome génitoadrénal pendant l'enfance) *Acta
ch scand* 1944 90 210

A sketch is given showing the blood supply of the
suprarenal glands an accurate knowledge of which
is necessary for operation on this organ. The supra-
renal gland is relatively very much larger in the
child up to 3 years of age than in the adult the por-
tion of kidney to suprarenal tissue being 3 to 1
in the child and 30 to 1 in the adult.

The technique of suprarenalectomy is described in
detail. The organ may be approached from in front
or behind. The abdominal incision is preferable in
large tumors but in operations for a hormonal syn-
drome without tumor the author prefers the lumbar
incision. The incision is made along the lower border
of the twelfth rib and this rib is resected. American
authors seem to prefer a vertical incision. The lum-
bar incision and resection of the twelfth rib may be
performed on both sides but the author thinks it
preferable to operate only on one side at a time. He
operated on 2 cases in this way with good results
while in a third case in which operation on both
sides was performed at the same time the patient
died of profuse pulmonary atelectasis and pulmonary
edema. He thinks this result may have been due to
the simultaneous removal of both twelfth ribs which
made ventilation of the lungs difficult.

The patient should be examined carefully before
operation to determine whether there is tumor or
hyperplasia. For 2 days before operation he should
be given a diet poor in potassium and rich in salt.
An abundance of carbohydrate and extract of sup-
rarenal cortex should be given before operation.
Glucose solution and suprarenal extract should be
given after operation also the length of this post-
operative treatment depending on the electrolytes
blood sugar blood urea and blood pressure. A phy-
sician should be in constant attendance on the child
for 4 hours after the operation, and a nurse for 4
days. In bilateral operations the left side should be
operated on first as the chances of finding a tumor on
that side are greater.

Four cases in which the author operated are dis-
cussed. In 2 there was a genitoadrenal syndrome
and in the 2 others a Cushing syndrome although
in 1 of these there was some doubt as to the differ-
entiation between the Cushing syndrome and the
genitoadrenal syndrome. There was recovery except
in the case mentioned. In this case there was a small
basophil adenoma in the anterior part of the gland.
In the other cases there was only hyperplasia. In
cases of bilateral hyperplasia bilateral resection

should be performed. If the hyperplasia is unilateral
the operation should be done only on the affected
side if indeed operation is performed at all in such
cases.

So far the treatment has not shown any great
effect in the cases mentioned except an improvement
in the mental condition of the patients.

ADOREY C. MORGAN M.D.

Smith C. G. W. On Urinary Lithiasis in Child-
hood. A Clinical Study of 71 Cases of Urinary
Calculi in Children. *Acta chir scand* 1944 90
170

This article discusses 71 cases of urinary calculi
in children collected from various hospitals in Copen-
hagen from 1929 to 1943 special emphasis being
placed on prognosis and treatment. Of these
patients 51 were male and 20 female almost three
times as many males as females. This corresponds
pretty closely to the figures of other authors for uri-
nary calculi in children and also to those in adults.
Therefore urinary calculosis in children is not near-
ly so rare especially in Denmark, as it has generally
been assumed to be and as considerable damage may
be done to the urinary tract by these stones it is
advisable to remove them surgically as promptly as
possible no matter what the age of the patient.

The age of the children at the time of diagnosis
was quite uniformly distributed from less than 1
year to 14 years of age. However if a study is made
of the time at which symptoms began it will be seen
that stone formation began at a much earlier age
than clinical experience would indicate. It occurs
to a great extent during infancy and this is the period
at which a study of the factors causing it should be
made. Eleven of these children had developed cal-
culi before they were 1 year old. Two-thirds of the
children (41) apparently had the stones before they
were 5 years of age and 25 before they were 3.
Most of these cases showed stones of the kidney
and ureter although the majority of the reports pre-
viously published showed that most of the stones
were in the bladder and urethra.

In 26 of the cases the stones were passed spon-
taneously and in 12 of these there was no recurrence.
In the others the lithiasis persisted. Among 33 cases
subjected to chemical analysis 31 yielded so-called
primary aseptic stones composed of calcium oxalate
urate, and phosphate while only 2 cases yielded in-
fected stones. Evidently infection is not of great
importance in the causation of urinary stones in
childhood. Anomalies of the urinary tract how-
ever are of great importance. Such anomalies were
found in 58 of these cases. Roentgenograms of sev-
eral cases are given in the original article.

Almost a third of these children had no demon-
strable changes in the urine. Normal urine there-
fore should not necessarily lead to a negative diag-

nesia. When pain occurs in the urinary tract, careful examination should be made by means of urography, pyelography, cystoscopy, and cystography.

In this material 63 operations were performed in 53 patients. Primary nephrectomy was performed in 7 cases, simple lithotomy in 36, and several operations were performed in 9 cases. Even very young children bear these operations well. There was only 1 death following operation in this series and this was in an infected case. If there is infection in the urinary tract, treatment should be followed up until the urine is sterile. Both indications and treatment should be conservative in serious bilateral cases.

Among 43 surgical cases re-examined later 34 showed no recurrence. There was recurrence in 9, or 21 per cent, the percentage of recurrence in infected cases being 29 and in noninfected cases 11.

AUDREY G. MURDOX M.D.

Köhler B. The Prognosis after Nephrectomy; A Clinical Study of Early and Late Results. *Acta ch. sc. d.* 944 9 7

A knowledge of the results of nephrectomy, especially the late ones, is very important in surgical urology, but heretofore a careful study of these results has not been made. This article presents a study of the follow-up examination of the patients upon whom nephrectomy was performed at the Maria Hospital in Stockholm from 1905 to 1934. They were 197 in number. Detailed case histories of some types of cases and tables showing the results of treatment are given, as well as an extensive bibliography on the subject.

The number of nephrectomies performed in Sweden is steadily increasing, because of improved diagnosis and greater confidence in surgical treatment. In 1938 545 nephrectomies were performed, or 1 to every 12,000 of the population.

A detailed discussion is given of what is known of the functional condition of the remaining kidney after operation. In this series of cases kidney tuberculosis and kidney tumor are not considered. The cases operated on were mostly cases of hydronephrosis, infection, and calculus.

There were 49 patients with hydronephrosis. Of these 4 died soon after operation and 1 could not be traced. Of the remaining 44, 17 later showed signs of disease of the urinary tract. Nephrectomy was performed for renal ectopia in 1 case and for rupture of the kidney in another. No secondary nephrectomy was necessary for complications following conservative treatment of ruptured kidney, a fact which argues in favor of conservative treatment of this condition. Nephrectomy was performed in 21 cases for infection not connected with concretions. Two of these patients died, and of the remaining 19 11 later had symptoms of disease of the urinary tract. Nephrectomy was performed on 3 patients with cystic kidney and 3 with a renal cyst. One patient operated on for cystic kidney survived for 21 years. Nephrectomy was performed for renal calculus in

103 cases, among these there were 7 postoperative deaths. Two patients could not be traced. Fifty-eight of the remaining 95 showed signs of disease of the urinary tract on later examination. Nephrectomy was performed on 6 patients with vascular disease. This indication for nephrectomy should be rare. Five patients with disease of the ureters were nephrectomized.

The operative mortality was 13, or 6.7 per cent. The mortality was considerably higher for males than for females, 10.6 per cent and 5.6 per cent, respectively. Some form of urological disease was demonstrable in 96 of the 184 patients who survived the operation; a table is given showing details of the nature of these diseases. Urinary tract infections occurred in 37 per cent of the nephrectomized females and 21 per cent of the males. Of 103 patients now living who were examined by means of non-protein-nitrogen determinations 4 had imminent or manifest uremia. Of the 56 patients tested for creatinine clearance 6 (10 per cent) had reduced renal function. For practical purposes it is sufficient to test the kidney function of nephrectomized patients by non-protein-nitrogen estimations and concentration tests. The risk of uremia was still remote in the majority of the patients with reduced kidney function. Blood pressure determinations on 111 patients showed hypertension in 61, or 55 per cent.

Life expectancy in nephrectomized patients depends on whether pathological symptoms persist in the urinary tract. Deaths from urinary-tract disease were found to be common in the patients who survived operation. It should be possible to decrease this risk by adequate treatment after nephrectomy. Some patients should be kept under continuous supervision after the operation. Even if the patient is clinically well some years after the operation there is still a possibility of complications such as the reformation of stones after nephrectomy for calculus.

AUDREY G. MURDOX M.D.

BLADDER, URETHRA, AND PENIS

Tauber R.: Stricture of the Female Urethra with Lymphopathia Venerea. *A. M. S. J.* 945 1

A colored woman, age forty-one, was admitted to the hospital complaining of great difficulty in voiding her urine. She stated that ten years ago on a very cold day she had to wait for a trolley car a very long time and arriving at the factory she felt cold "up to the navel." She was unable to pass urine, and on her way home she started dribbling. Her family physician could not pass a catheter and ordered medicine which improved the condition temporarily. Since this time the patient had been under medical care.

On physical examination the urethra was found to be extremely narrowed and allowed only the passage of a filiform urethral catheter by which the greatly overdistended bladder was evacuated. The Wassermann reaction was negative.

GENITAL ORGANS

Munger A D The Treatment of Carcinoma of the Prostate by Irradiation *Radiology* 1945 45 31

In his introduction the author emphasizes the high incidence of prostatic carcinoma (from 14 to 20 per cent of all prostatic tumors) and its bad prognosis due to the absence of symptoms which prevents early diagnosis and also due to the early formation of metastases. He gives a clinical classification of this condition (based upon a previous study) which allows a more accurate prognosis. He acknowledges the significance of a rise of the acid phosphatase serum level, the importance of sterilization and the role of hormone treatments but he does not share Huggins' opinion that orchiectomy is the method of choice. He believes that x-ray sterilization combined with regional irradiation is more effective. In order to clarify this point the following series of 27 cases of histologically proved carcinoma of the prostate was treated during a two-year period ending May 1943. (The results refer to the time of presentation of this paper September 1944.) The cases were divided into 3 groups. The first was treated by resection (mainly for biopsy purposes) and by orchiectomy. Of the 7 cases so treated only 2 were successfully stabilized. Two of the patients died of metastases, and 3 had metastases when first seen.

The cases in group 2 were treated by resection and regional and testicular irradiation. Of the 12 cases so treated 10 were successfully stabilized. Two patients died of metastases but 1 of these had discontinued the treatments. Seven had metastases when first seen.

The cases in group 3 were treated by resection, regional irradiation, testicular irradiation and estrogen therapy (ethinyl-estradiol). Of 8 cases so treated 7 were successfully stabilized. The subjective well-being of the patients was superior to that of other groups. One patient died of cerebral hemorrhage.

The acid phosphatase serum level was studied in all of the patients.

The author arrives at the following conclusions:

1. Treatment consisting of resection, testicular irradiation, local irradiation and estrogen administration gives the best results.
2. An elevation of the acid phosphatase level is a reliable indicator of activity but its absence does not prove the contrary.
3. The experience of other authors that x-ray castration was incomplete is explained by their giving an insufficient dose to the testes.

The author gives daily doses of 300 roentgens, i.e. a total of 1800 roentgens in six days to the testicles. He uses 200 kv. (peak) 0.5 mm. of copper plus 1 mm. of aluminum filter H.V.L. 9 mm. of copper. This is followed by a more or less conventional deep x-ray therapy to the pelvis through 4 portals up to a depth dose of 5500 roentgens in the midpelvis in fractionated doses. This constitutes the aforementioned regional irradiation.

The only positive finding in the case was the positive reaction to the Frei test which proved to the author that the patient was suffering from lymphopathia venerea.

Lymphopathia venerea is a disease of the lymph channels and of the nodes which is due to a filtrable virus and gives a positive reaction to the Frei test.

The lymphopathic infection of the urethral mucosa may occur in different forms: erosion, superficial ulcer and seropurulent inflammation.

It should be emphasized that there is a variation in the form of the disease in men and women as a result of differences in the distribution of the lymphatic drainage.

In the male most of the lymph channels of the genitalia drain into the inguinal nodes and some drain into the deeper iliac nodes. In the female on the contrary only the lymph from the clitoris and external vulva drains into the inguinal nodes while the supply from the vaginal mucosa (and especially from the posterior vaginal wall) drains into the lymph nodes around the rectum where there are three lymph plexuses extending together up in the rectum to a height of from 4 to 6 cm. Consequently rectal strictures are much more common in females than in males who suffer from this disease.

The lymphatics of the whole urethra in the female pass to the hypogastric nodes. This is the reason that we do not find enlarged inguinal nodes in case of involvement of the urethra alone. A stricture of the urethra caused by lymphopathic disease can be explained only by a primary involvement of the urethral mucosa and the lymphatics in the immediate neighborhood. In the urethra a primary involvement of the mucosa takes place and the infection spreads through the lymph channels from the urethral mucous membrane and forms scars with stricture formation of the urethra.

The diagnosis of lymphopathia venerea has been greatly simplified by the discovery of Frei, announced late in 1925. This specific cutaneous sensitivity lasts for many years, perhaps during the life of the patient; in other words the patient develops an allergic state.

The fact that a patient is suffering from lymphopathia venerea does not prove that the lymphopathia venerea stands in causal relationship to her urethral stricture. A case of proved lymphopathia venerea may induce urethral stricture following trauma during a delivery and in such a case one the combination of stricture of the urethra and a positive Frei test.

If the stricture is not too tight nor spread over too large an area it may be treated by rapid dilatation putting the patient under gas anesthesia and passing Hegar dilators until the canal is enlarged from 2 to 3 mm. in diameter or up to the size of the average glass catheter from 6 to 7 mm.

The patients should be warned that recurrences are common and that for this reason they should return several times a year for dilatation.

JOHN A. LOFF, M.D.

determination resistance to spermaticides viscosity and rate of liquefaction are made as a rule although none of these factors has as yet been proved of decisive import in matters of fertility. The material is then prepared for microscopic study.

A thin film is made from well-mixed seminal fluid (thorough mixing is essential as immotile sperm sinks rapidly on standing). Dense specimens may be diluted with an equal quantity of Ringer or other isotonic diluent. The sperm is fixed by inverting it over a drop of 2 per cent osmic acid in a watch glass for five minutes. The seminal fluid is then coagulated by flooding the slide with Schaudinn's fluid for one minute. After fixing the slide is rinsed in alcoholic iodine washed in running water for ten minutes, counterstained in 1/2 per cent rose bengal (either the watery or the 70 per cent alcoholic solution for one minute), dehydrated and mounted.

The slides are examined under 1/12th objective, 200 being counted in routine practice. The sperm when counted is classified as (a) normal or abnormal as to the head with subclassifications into (b) amorphous, (c) monster, (d) double, (f) pin, and (g) round pear or tapering or as to the middlepiece and tail, with subclassification into (h) collar (i) bent, (j) thick neck, (k) double tail (l) folded tail and (m) ring forms. These letters correspond to those on Figure 1. The authors studies indicated that in the fertile male the abnormal forms should not comprise more than 35 per cent of the total sperm count.

The total sperm count per cubic centimeter of seminal fluid the motility and the "viability" are determined in seminal fluid warmed in an incubator for one hour to 37 C. The fluid is diluted appropriately and counted on a warmed Thoma slide. One drop is counted for the number of immotile and feebly motile sperm, and another drop, in which the sperm is immobilized by osmic-acid fumes is given a total count, and the difference between these two counts designates the number of fully motile sperm. The authors consider that the total figure, the so-called density should be at least 50 million sperm per cubic centimeter of seminal fluid in a fertile male and the number of fully motile sperm should range from 50 to 10 per cent according to the time elapsed (from one half to seven hours) since the specimen was procured. A similar estimation is made after three hours and after five hours of incubation (the so-called index of viability). Viability is judged by the ratio of the percentage of motility after three and after five hours of incubation in diluting fluid to that after one hour the sum of these two ratios being designated the "viability ratio." If no fall in activity occurs during the five hours the viability ratio would be 2. The authors state that in the fertile male the viability ratio one half hour after the specimen of semen fluid is procured should be 2.5. In one-half to three hours it may drop to 2.25, in three to five hours to 2.0 and in five to seven hours to 1.5. In 236 clinical cases seen by the author at Exeter in South England

examination was carried out as described and in an attempt to establish a means of assessing the fertility the cases were designated an A for each of the four factors just discussed when they were above the minimum figures given for probable fertility and a B when less than that figure indicated a probable subfertility. In the 236 cases there were 31 with a rating of AAAA 63 with AAAB 51 with AABBB and 50 with BBBB.

Applying these criteria and taking into consideration the wife's degree of fertility or subfertility in each case the authors are of the opinion that male subfertility does not become of primary importance unless the results of the semen analysis are found to fall below these minimal values in all four factors (about 20 per cent of all cases). In this 20 per cent, treatment with testosterone propionate, gestyl, synaplofin, methyltestosterone tablets, testosterone implants, ambion A androgens or thyroid did not seem to get any results. The analysis is of relative importance when the values fall below the minimum in at least two of the factors (about another 40 per cent).

For the immense amount of detail concerning the minor factors affecting these general considerations and the authors' recommendations for further work in this field the reader is referred to the original article.

JOHN W. BARRETT, M.D.

McMartin, W. J.: Urological Aspects of Filariasis. *J. Urol. Balt.*, 1945 54 62.

Filariasis has infected thousands in our armed forces stationed in the Pacific area.

The disease in these men is characterized by episodes of lymphangitis and lymphadenitis with the majority of the patients showing genital (scrotal) involvement.

Civilian urologists will be confronted with the problems of differential diagnosis of intrascrotal pathological changes caused by filariasis from intrascrotal pathological changes usually encountered in the United States.

There are many members of our armed forces who have filaria and fear the onset of elephantiasis despite attempts of medical officers to dispel their fears. We can do a great deal to ease these patients' minds by education pertaining to the characteristics of the disease.

There is no specific drug in the treatment of filariasis. Removal of the patient to a temperate climate and away from the chance of more infection is most important.

Rest elevation of the affected parts and cold applications is the treatment of choice in episodes of exacerbations of the disease.

Research on the treatment of filariasis is constantly being carried out by very competent medical personnel. Army and Navy. Excellent results have been reported in the literature soundly based on the knowledge of the pathogenesis of the disease. It is when and if complete postoperative treatment can be done on patients who

have filariasis or who give a history of having had filariasis at some time during their life.

Filariasis will not become a public health problem in the United States.

Permanent disability as a result of filarial infection among our armed forces will be a rarity.

JOHN A. LOFF, M.D.

Hjort E. and Stetvold, K. Postoperative Bacterial Findings in the Lower Urinary Tract after Suprapubic Prostatectomy. *Acta chir scand* 1945 92 115

The two chief dangers in suprapubic prostatectomy are infection and hemorrhage. To combat infection effectively it is necessary to have a thorough knowledge of the types of bacteria most commonly found in the urine. Therefore the authors made daily bacteriological examinations of the urine for two weeks after prostatectomy in 34 cases. They found that the predominant bacteria were the *Escherichia coli* and the *Streptococcus fecalis*, the former being found in 32 cases and the latter in 28. After being demonstrated for the first time these bacteria appeared in every later test. In 2 cases the *Escherichia paracoli* and the *Bacillus alcaligenes fecalis* were found instead of the *Escherichia coli*. The *Bacillus proteus* was found in 5 cases, the *Staphylococcus aureus* was found in 3 cases and the *Pseudomonas* in 1 case.

As the bacteria found in the urinary tract were practically always intestinal bacteria it seems probable that the source of infection lies in the intestine. This infection from the intestine takes place very quickly even when the most careful asepsis is practiced. In 24 cases the urine contained intestinal bacteria on the day after the examination, and all of the specimens of urine were positive for intestinal bacteria on the fifth day. The bacteria are probably carried from the intestine to the bed of the prostate by the blood and lymph. Some experiments made by the authors show that it is improbable that the urethra or the skin are the source of infection.

In 35 cases cultures were made from the enucleated prostate gland; in 12 cases they were positive and in

23 cases negative. They were not positive any more frequently in the cases with prostatitis than in those in which there was only an adenoma. In some cases the prostate gland contained bacteria when there were none in the urine. Examinations of punctate from the exudate in cases of epididymitis showed that this disease is not necessarily caused by the bacteria in the urine but may come from some other source, possibly the urethra.

Two cases of psychosis following prostatectomy are described. They were probably caused by bacterial toxins.

AUDREY G. MORGAN, M.D.

Prince C. L. and Richardson E. J. Jr. AP-43, a New Antispasmodic for Use in Urology. *J. Urol. Balt.* 1945 54 75

A new synthetic antispasmodic, AP-43, was used in a series of 61 cases in which spasm of the smooth muscle of the urinary tract was thought to be the major cause of pain.

This drug was found to be extremely effective in relieving pain resulting from ureter catheterization and retrograde pyelography.

AP-43 will promote the passage of a substantial number of ureteral calculi, when their size is not such as to preclude their spontaneous passage. With this type of calculus AP-43 will relieve pain in the great majority of cases. Apparently, unless pain is present with the calculus, the drug is not effective in assisting the passage of the stone.

In 13 of 10 cases of severe bladder spasms AP-43 gave complete relief.

It is suggested that AP-43 is of value when used under the following circumstances: (1) prior to retrograde pyelography to prevent postpyelogram pain; (2) prior to cystoscopy as an aid to ureter catheterization; (3) prior to cystoscopic manipulation of ureteral calculi to give greater relaxation of the ureter.

Undesired side effects are uncommon and usually mild in nature when they occur. There was no evidence of cumulative toxic effects in this series of cases.

The drug may be given effectively either by mouth or intramuscularly.

JOHN A. LOFF, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Weeden W M and Stein H D : Experiences with Injuries and Diseases of Bone in World War II
1 *n Surg* 945 3

In an evacuation hospital which, by force of circumstances, acted as a general hospital the authors treated numerous cases of injury and disease of practically every bone in the body.

Most fractures of the clavicle responded to simple treatment—a cruciate splint, holding the shoulders back and leaving the arms free. In general this has proved satisfactory. In cases of osteomyelitis, the most rapid closure was obtained by removing the whole involved portion.

Fractures of the scapula require little treatment beyond strapping and rest of the part. Osteomyelitis may be rather extensive and in one case required the removal of the entire body of the bone.

Fractures of the ribs, without pleural or pulmonary damage are also easily cared for. Infection may be extensive, and may spread rapidly.

Fractures of the vertebrae were treated by plaster jackets and rest for a period of four months, although so prolonged a rest may be unnecessary. Transverse-process fractures respond quickly to several weeks of rest in a light plaster jacket, or to merely adhesive strapping.

The hanging cast¹ for fractures of the shaft of the humerus has given excellent results. Immobilization for from six to eight weeks proved sufficient, and early treatment with heat and massage helped to restore full motion.

Fractures of the olecranon process or the epicondyles are best treated by open reduction and accurate replacement of the fractured fragment. Early active motion is necessary. When complete ankylosis is unavoidable, an effort should be made to accomplish it with the arm in about 80° flexion.

Fractures of the shaft of the femur have been treated frequently with a three way splint—a 6-inch wide plaster splint applied posteriorly, extending from the tip of the scapula to the end of the toes, a second similar splint extending laterally from the lower ribs to the tip of the external malleolus, and a third splint applied anteriorly running obliquely from the anterior superior spine to the inner surface of the knee. This type of splint is effective, comfortable, easily adjustable, less likely to cause pressure sores, and can be removed in part for early muscle massage. *SAMUEL KAHY, M.D.*

Weens, H. S., and Brown, C. E.: Atrophy of the Terminal Phalanges in Clubbing and Hypertrophic Osteoarthropathy. *Radiology* 945 45 57

Hypertrophic osteoarthropathy is a condition well known to clinicians and radiologists alike. Its

clinical manifestations, however, differ from its roentgen findings by their location. The physical examination reveals that the soft tissue swelling is most marked around the terminal phalanges of the fingers and toes (clubbing) whereas the roentgenological findings which consist mainly of penosteal new bone apposition, predominantly involve the distal shafts of the ulnae radii tibiae and fibulae, occasionally extend to the proximal phalanges but almost never affect the terminal phalanges.

The authors refer to the small number of previously reported cases which showed atrophic bone changes in the terminal phalanges and add 2 of their own. The first case—that of a fifty nine year-old colored female displayed marked destruction of all the terminal phalanges thinning of the shafts of the middle phalanges of the toes and hypertrophic periostitis of the long bones. There were no signs of pulmonary or heart disease. The second patient, a colored male thirty years of age, was afflicted with congenital heart disease. The only x ray finding in his case was atrophy of the ungual processes of the terminal phalanges of his toes.

The authors conclude that this bone atrophy was preceded by the more commonly known hypertrophic changes mainly because histological and roentgenological examinations by others have shown that lacunar absorption and osteoporosis of the newly formed subperiosteal bone occur in advanced cases. (The explanation that pressure from neighboring soft tissue swelling or from dilated pulsating small blood vessels causes the erosion of the terminal phalanges has not been confirmed by pathologists according to the authors.) In the differential diagnosis of atrophic or destructive changes of the terminal phalanges, Raynaud's disease, scleroderma, psoriasis, syringomyelia, tabes dorsalis and leprosy are discussed. *GERHART S. SCHWAB, M.D.*

Kautz, F. C. Capsular Osteoma of the Knee Joint. *Radiology* 945 45 62

The author presents 4 cases of benign osteoma of the knee joint and concludes that osteoma of the knee joint as well as of other joints such as the elbow hip shoulder and ankle is rare.

Roentgenograms reveal characteristic changes, differing from those in other arthrogenic tumors, such as chondromatosis or joint mice. The absence of any bone connection between the tumor and the adjoining bony structures can readily be demonstrated. The blood vessels and surrounding skeletal parts are never invaded. A well-delimited shadow of bony density with cancellous and sometimes spongy pattern is usually found with small irregular areas of increased radiolucency. There is a more or less continuous dense outer shell and the shape of the shadow may be that of an hourglass, an Indian club, an egg or of the patella.

The history usually ranges over many years and often dates back to traumatism during the age of bone growth with repeated mechanical damage to the knee in the interval. The size of the tumor as shown on roentgenograms and at operation is barely in proportion to the low grade functional impairment and clinical complaints. Symptoms and signs seem to become more marked as the patient enters middle age.

The etiology is still obscure. The authors observations and those of others seem to support the opinion of Kienbock that infection plays no part and that a single injury can hardly be the cause of the condition. Since repeated traumatism of occupational or athletic character can be traced over many years in the majority of the patients it can be assumed that mechanical influences induce a proliferation of a normally dormant biologically polyvalent and potentially bone forming synovial tissue. Whether the primary damage of the synovial cells consists in a constitutional embryonal aberration or a traumatic detachment with subsequent implantation before the termination of bone growth cannot be decided. Insidious proliferation of dormant embryonal-cell rests with metaplastic changes is well known in tumor pathology. A similar origin of the joint osteoma from synovial implantations under the impact of repeated mechanical damage over a long period of time conforms well with the present conception of tumor formation.

DOUGLAS R. MORTON, M.D.

Hartz, P. H.: Cancerous Synovial Tumors. *Arch. Path. Chic.* 1945 40 88

Three cases of a cancerous synovial tumor are presented. In 2 cases the tumor originated in the knee joint and in 1 case in the foot probably from a tendon sheath. In 1 case the tumor cells were uni-laterally differentiated and resembled histiocytes whereas in the other 2 cases the tumor showed a complex organoid structure with cells resembling epithelium. In all 3 cases the patient was treated by amputation. In 2 cases the cancerous nature of the disease was recognized only by microscopic examination.

ROBERT I. MONTGOMERY, M.D.

McLaughlin, H. L.: Lesions of the Musculotendinous Cuff. *J. Am. M. Ass.* 1945 128 563

Sixty proved ruptures of the short rotator cuff of the shoulder form the basis of this report. Eleven of the patients were under forty years of age and 5 were under thirty years of age. Nineteen of the patients were women.

Most of these ruptures occurred in well used shoulders in individuals past middle age. It is reasonably certain that sufficient degeneration at times so weakens the tendon for strains that it may rupture without significant cause.

Early repair is not warranted in the average case because early repair has been no easier to accomplish than late repair. The results of early and late repair have been identical. The symptoms in a large per-

centage of cases showing a clearcut clinical picture of rupture subside spontaneously under conservative therapy to such an extent that repair never need be done. Since rupture almost always takes place through a degenerating portion of the tendon efficient union of the repair can be expected only after the degenerated edges of the tear are excised. Whether operation is done early or late excision of the periphery is equally necessary. It has been demonstrated that the tendons making up the upper segment in any given position of humeral rotation are an essential factor in both initiation and maintenance of abduction and that the function of the individual intrinsic muscles is interchangeable in this respect. Dislocation at the shoulder accompanied by a fracture of the greater tuberosity almost always is accompanied by a torn cuff.

More than 100 calcific deposits of the shoulder have been explored. Only 1 was accompanied by a torn tendon. The only definite indication for exploration consists of pain or disability sufficient in duration or severity to make the procedure worthwhile from the patient's point of view. A plan was followed for the diagnosis and evaluation of the torn shoulder cuff. Sixty-four shoulders with a pre-operative diagnosis of rupture were explored. The diagnosis was incorrect in 4 cases.

RICHARD J. BENNETT, JR., M.D.

Björkroth, T.: Subcutaneous Rupture of the Distal Tendon of the Musculus Biceps Brachii. 2 Cases (Die subkutane Ruptur der distalen Sehne des Musculus bicipitis brachii 2 Fälle). *Acta chir. sc. sc.* 1943 89 30

Two cases of rupture of the distal tendon of the biceps brachii muscle are reported. Both occurred in white males with powerful muscular development. The one a young man of 38 years slipped and fell on the street and in attempting to "break his fall" with his right arm experienced a tearing sensation followed by pain and loss of muscular power in this limb. Later medical examination brought to light the abnormally elevated location of the bulge of the biceps, absence of the taut distal tendon and loss of power in flexion at the elbow and in supination of the forearm. The second man was 58 years old; he had attempted to lift a heavy cask and exhibited practically the same symptoms and findings. In both patients operation was performed 4 and 5 days respectively after the injury.

An incision was made in the bend of the elbow, blunt dissection was carried out down between the muscles, the vessels and nerves being held aside by blunt hooks. The tuberosity of the radius was brought forward and rendered accessible by extreme supination of the forearm; a hole was drilled through it near its base and a linen thread which had previously been attached to the ruptured tendon end was passed through this drill hole which pulled the tendon stump down to the tuberosity where it was secured. For the next four weeks the arm was held at an angle of 90 degrees and in maximal supination.

in a plaster cast. The result was perfect return of muscular function and power.

At microscopic examination a bit of each tendon revealed noticeable degenerative and regressive changes with a suggestion of inflammatory response in the older patient. However the author leaves open the question as to whether the changes were due to the injury itself or to a preceding condition, such as brachioradial bursitis.

JOHN W. BRENNAN, M.D.

Howorth, M. B.: *Echinococcosis of Bone. J. B. N. Surg.* 945: 37-401.

The author presents a case report of echinococcosis of bone with several accompanying roentgenograms (Figs. 1 and 2).

There are numerous cases of echinococcus disease of bone in the world literature (an estimated 1,000) but the disease is rare in the United States.

Bone involvement occurs in about 1 per cent of cases of the disease. Pain is the most common symptom of bone involvement, and is due to leakage or to pathological fracture.

Aspiration or puncture of the cyst yields the characteristic fluid and often scolices or fragments of laminated membrane but it should not be practiced because of the dangers of sensitizing the patient, of anaphylaxis if he is already sensitive, or of producing secondary cysts by implantation of the scolices which escape into the tissues. The fluid is clear and limpid or milky unless stained by other fluids. The scolices are white granules just visible to the eye.

Daughter cysts are milky white opalescent semi-transparent with yellow scolices hooklets or fragments of laminated membrane may be found in the putum urine 1 week after rupture of a cyst. Other laboratory diagnostic tests are discussed.

The differential diagnosis depends largely upon the possibility of echinococcus disease upon laboratory tests and upon the roentgenographic appearance. A negative Mantoux reaction will rule out tuberculosis. Calcium, phosphorus and phosphate determinations may help in distinguishing osteitis fibrosa cystica or Paget's disease. The white blood count, the erythrocyte sedimentation rate and the temperature distinguish osteomyelitis (except cysts with secondary infection). The slow silent course is indicative of echinococcosis rather than of malignancy.

Treatment has been unsatisfactory to date. Marsupialization or sterilization of the cyst may sometimes be successful. Roentgen irradiation has failed. Removal of the entire diseased area has removed the disease, but it is mutilating. Insertion of bone chips will not be successful unless the disease has been eradicated. Amputation is the choice of treatment in selected cases. ROW ET P. MORTON, M.D.

Jones, G. B.: *The Pathology of the Ruptured Plantaris Muscle. B. B. M. J.* 945: 1-876.

The case of a soldier thirty-one years of age who was thrown from a motorcycle is reported. He felt intense pain in the left calf and thought he had been struck a direct blow on the leg but examination

Figs. 1 and 2. Roentgenograms of the right knee show a large polycystic lesion of the lateral femoral condyle with sharp margins, and smaller cysts above the intercondylar notch, erosion posterior to the notch and possibly at the distal lateral margin of the lateral condyle, and moderate dense swelling of the capsule. No productive or periosteal reaction is apparent.

showed that he had slid across the road and had been brought to a stop when the sole of his foot struck the curb which had caused forced dorsiflexion of the ankle. There was an incised wound of the Achilles tendon 3 inches above the ankle joint. The plantaris tendon lay slack in this wound and traction on it delivered the tendon and about half of the muscle belly which had been ruptured transversely at about the middle.

This case and experimental work show that this is the usual mechanism of ruptures of the plantaris. They are not caused by direct violence but by forcible dorsiflexion of the ankle. Because the muscle belly is very short and the tendon very long the length of the belly being only about one-fifth the total length of the muscle and tendon the belly is subjected to much greater tension than the other calf muscles and ruptures much more easily.

AUDREY G. MORGAN M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS ETC.

Du Tolt G. T., and Enslin T. B.: Analysis of 100 Consecutive Arthrotomies for Traumatic Internal Derangement of the Knee Joint. *J. Bone Surg.* 1945 37 412

An analysis has been made of 100 consecutive knee arthrotomies performed on European miners working underground in the Witwatersrand Gold Mines.

The routine of clinical diagnosis operation and postoperative care is described.

The operative findings have been analyzed. In 4 cases no meniscal lesions were discovered at operation. In 82 cases tears of the medial meniscus were found and in 9 cases tears of the lateral meniscus were seen. There were double tears in 5 cases and discoid menisci in 2. Of 97 torn menisci 49 were of the bucket handle type.

The operative findings have been correlated with the signs found at examination.

Pain at the anteromedial joint line was found to be of considerable diagnostic significance. Absence of such pain contraindicated arthrotomy for a meniscal lesion.

It was shown that locking is frequently, but not always due to a meniscal lesion. A stub of anterior cruciate ligament was the cause of locking in 1 case.

Meniscal damage may exist in the absence of wasting.

Fouche's hot spot on the medial facet of the patella is described.

The crushing sign is found to be not entirely pathognomonic of meniscal damage.

Erroneous diagnoses and operative complications have been analyzed in some detail.

The end results of treatment are given. The disability assessments averaged 1.6 per cent for the whole series.

The penalty of delay in operation has been found to vary greatly according to the type of lesion.

The findings in the authors' investigation favor early and total meniscectomy if an incontrovertible diagnosis has been made.

From the medicolegal point of view it should be accepted that a very minor trauma may produce a torn meniscus. Although clinical manifestations following trauma may be delayed for months lack of pain does not exclude the possibility of a tear.

The postoperative routine is reported as follows.

The foot of the bed was raised on 8-inch blocks. On the second day active foot and ankle movements were started and on the third day, active quadriceps contractions were begun. Straight leg raising ten times per hour was initiated on the fourth day and active flexion to the extent permitted by the dressing was allowed on the seventh day. On the twelfth day the stitches were removed and the patient was seated in a wheel chair. Thus the knee was unconsciously flexed to 90 degrees. The quadriceps drill was maintained. The patient was usually able to lift his knee 200 times at one sitting on the fourteenth day and beginning at this time he was allowed to attempt walking with the aid of a cane. On the sixteenth or seventeenth postoperative day the patient was formally discharged but he continued in daily attendance in the outpatient department traveling by bus or tram to the hospital. From the fourth week, the patient was instructed to swim ride a bicycle do antigravity weight and pulley exercises or stationary rowboat exercises and to walk several miles daily. Work was usually resumed at the end of the sixth or the seventh week.

ROBERT P. MONTGOMERY M.D.

FRACTURES AND DISLOCATIONS

Tordoir, B. M. and Moeya, E. J.: Medullary Nail for Fractures. *J. Am. Med. Ass.* 1945 138 792

The use of a V2A steel nail was introduced in 1940 by Kuentscher. In 1944 Boehler published his book which gave the results with the use of the V2A nail in 500 cases. The type of fracture which responds best to this method of treatment is the transverse fracture of the diaphysis as the nail is fixed in both epiphyseal ends without injuring the articular cartilages. A few days after this operation the patient is able to walk about and leave the hospital. This method gives an exact reduction of a transverse fracture. The nail may be used in compound fractures if they are treated within a period of 10 hours. It has also been used in the treatment of pseudarthroses.

Before the operation an x-ray examination should be made of the length of the bone and the width of the medullary cavity. Reduction is carried out on a special frame under fluoroscopic control. In the femur an opening is made in the trochanteric fossa with a piercer and a thin stiff nail is pushed through the medullary cavity and beyond the fracture line into the distal fragment. The Kuentscher nail is slipped over the thin wire, and the wire is then removed. For fractures of the tibia a weak spot just

In the second group a perfect cure was obtained in 12 of 13 cases. Only 1 patient had a considerable varus position of the broken elbow. In 3 cases the reduction was poor and yet the function was excellent.

In the third group 12 out of 22 patients treated in a conservative manner had perfect function while 18 underwent an operation and only 3 of these had impaired function. In 1 case the operative reduction failed and yet the functional result was excellent.

The author highly recommends roentgenograms taken in anteroposterior direction with the elbow flexed because only this method furnishes information as to the rotation of the peripheral fragment in relation to the humerus.

As a rule periosteum remains attached to the short distal fragment but the sharp end of the long proximal fragment becomes denuded. The author is of the opinion that the absence of periosteum is responsible for the gradual disappearance of this sharp end. No limitation of flexion was observed in patients in whom, due to an unsuccessful reduction the proximal fragment remained located entirely in front of the distal fragment.

Patients with the elbow in a varus position had no complaints as to function and were occasionally operated on solely for cosmetic reasons. Cubitus varus may follow immobilization of the fracture in supination.

The author is opposed to the use of slings or plaster of Paris splints in cases in which the fragments have lost contact with one another.

A valgus position or ischemia was not found in the author's material. JOSEPH K. NICHOL, M.D.

Westerborn, A. Nailing in the Marrow Cavity in Cases of Recent Fracture and Pseudarthrosis. Report of 28 Cases. *Acta chir scand* 944, 90-89.

In 1940 Kuntscher reported his method of treating fractures by inserting a nail into the marrow cavity. At first it was severely criticized but later quite widely adopted in Germany. The 18 cases reported by Westerborn, 14 of recent fracture and 4 of pseudarthrosis are the first cases published from the Scandinavian countries.

The principle of the method is to fix the fragments after reduction by inserting a nail into the marrow cavity. As the nail is driven in from an incision at a distance from the fracture open reduction is not necessary. It is not a large round nail that fills the marrow cavity but a U or Y-shaped nail that acts in about the same way as the 3 flanged nails used in fractures of the neck of the femur. It touches the endosteum only at three small points and therefore does not injure it or the marrow but produces very firm fixation. An illustration of the nail in place is given in the original article.

This method can be used in all transverse, oblique, and spiral fractures of the long bones especially of the femur. For the femur the nail is inserted from the upper surface of the trochanter either through

the skin or through a small incision. In the other long bones a small hole must be bored in the cortex at a distance from the fracture. Kuntscher advocates bloodless reduction but this is not always possible. The insertion of the nail must be made under fluoroscopic observation or checked by several roentgenograms. A number of typical cases are described and illustrated with the roentgenograms.

As it is unnecessary to expose the fracture in this method there is little danger of infection. If infection occurs it results in localized osteitis, never in diffuse osteomyelitis. There is little risk of fat embolism. Only 2 deaths from this cause have been reported in the literature. Bone healing occurred promptly in all of the author's cases of recent fracture.

He had good results in the cases of pseudarthrosis also. The method ensures absolute stability and permits of early weight bearing, two conditions necessary for healing. The ends of the bones should be freshened and any tissue between them removed. Six of the cases of pseudarthrosis were in war veterans and involved the femur; they had persisted for from 1/2 to 3 years and resisted other methods of treatment. Bone healing took place in all 6 cases. Osseous healing occurred within 3 months in 3 cases of pseudarthrosis of the humerus. Four cases have been operated upon so recently that the final results cannot be judged. AUGUST G. MORGAN, M.D.

Sandegard, E. Fracture of the Lower End of the Humerus in Children—Treatment and End-Results. *Acta chir scand* 943, 89.

At the Children's Hospital in Göteborg, Sweden where the author is Surgeon-in-Chief, the treatment of fractures of the elbow has been different from that usually described in the literature. He discusses 157 cases of fracture of the lower end of the humerus seen from 1909 to 1940. These included 164 cases of supracondylar fracture, 46 of medial epicondylar fracture, 40 of lateral condylar fracture, 4 of medial condylar fracture, 3 of transcondylar fracture but none of epicondylar fracture. The latter are extremely rare while comminuted fractures and T and Y-shaped fractures are practically never seen in children as they usually occur only when there is a certain degree of bone fragility.

Of these patients 189 were re-examined later. Most of them had been treated surgically. Fixation as a rule had been carried out with Risser's stainless steel nails which proved very effective. These were always extracted within three weeks. Catgut is not strong enough for operations on bone.

Two-thirds of the cases of supracondylar fracture were treated surgically. The forearm had to be immobilized in semipronation after operation because of the risk of allying of the fragments. The functional results were very good but a considerable number of cases showed cubitus varus and a few cubitus valgus.

Great emphasis is placed on the necessity for accuracy in reduction. Faulty reduction is the

cause of practically all the pathological changes that take place at the angle of the elbow after operation. Accurate reduction is sometimes quite difficult in these cases. And a excellent results are sometimes obtained by conservative treatment; operation can not be recommended unconditionally except in very stubborn cases.

Over 60 per cent of the cases of lateral condylar fracture were treated surgically. The results were very good and extirpation of the fragment was not found necessary in any of them. As there is a risk of pseudarthrosis in these cases with conservative treatment, operative reduction and fixation is recommended.

Because of the necessity for exact reduction in intra-articular fractures, extraction of the fragment is necessary in most cases of medial condylar fracture and transcondylar fracture. Good results are obtained with this method.

Generally it is not necessary to extract the fragment in medial epicondylar fractures. Immediate repair of the torn capsule and ligaments is possible by a very simple operative technique and good results are obtained.

Röntgenograms of a number of illustrative cases are given in the original article and a useful method of interpreting roentgenograms is discussed.

AUDREY G. MORGAN, M.D.

McKeever, F. M.: Fracture of the Femur in Adults. *J. Am. M. Ass.* 1945 128 1006

McKeever reports his observations on 47 patients suffering from closed fractures of the shaft of the femur in a military group between the ages of eighteen and forty. While the author did not initiate the treatment instituted, all patients were eventually placed under his care. Twenty three patients were treated by suspension and skeletal traction (Kirchner wire or a variation of the Steinmann pin). Open reduction was done in 17 cases—in 7 of these it was used after other methods failed (in the surgeon's opinion) to produce satisfactory position.

Seven patients were treated by external skeletal fixation with the use of some mechanical device. All patients were followed up from six and one half to twenty four months. The average period of time elapsing between the injury and the date of evaluation was twelve months. The average period of recumbency for patients treated by internal fixation was one hundred and eighty five days; by external fixation one hundred and sixty-eight days; and by traction one hundred and forty five days. The period of protection is the time between the injury and that when the patient is able to bear full weight without braces or crutches. The average time of total protection in the group treated by traction was two hundred and nineteen days, of those treated by plating two hundred and sixty six days and of those treated by external skeletal fixation three hundred and seventy days.

The roentgen evidence of bony union appeared in an average of two hundred and thirty three days in

23 femurs treated by traction. In 1 patient treated by internal fixation it was three hundred and three days and in 7 patients treated by external skeletal fixation it was three hundred and sixty four days. The criteria for bony union are obliteration of the fracture line and re-establishment of the bony trabeculae. No patient treated by traction had any loss of motion in the hip, ankle or foot. The average arc of flexion of the knee in 23 patients treated by traction was 101 degrees. In 17 cases treated by internal fixation the average arc was 85 degrees and following external fixation it was 78 degrees.

There was no loss of length in patients treated by external skeletal fixation but 3 patients, or 17 per cent, who were treated by internal fixation and 5 patients or 21 per cent who were treated by traction showed varying amounts of shortening. In 1 patient this shortening was sufficient to produce disability.

The results of treatment as judged by disability resulting from shortening of the extremity from loss of motion in the knee and other joints, and from the degree of muscular atrophy in this group showed that both external fixation and internal fixation were definitely inferior to traction.

Complications were most frequent in the group treated by open reduction and internal fixation. The complications included osteomyelitis, postoperative infection, thrombophlebitis, nonunion, broken and bent plates and palsy of the peroneal nerve. By percentages, 13 per cent of the complications occurred in patients treated by traction, 53 per cent in those treated by internal fixation and 57 per cent in those treated by external fixation.

From these studies McKeever points out that the safest method of treatment for fracture of the femur for the average surgeon in the average hospital is traction, and that open reduction should be reserved for those cases in which there is definite evidence of soft tissue interposition. The general use of apparatus designed for external fixation and ambulation is likely to delay union and carries the great risk of producing osteomyelitis at the sites of the fixation pins.

BENJAMIN GOLDMAN, M.D.

Moberg, E.: On the Operative Therapy and Prognosis in Fracture of the Patella. *Acta chir. scand.* 1944 90 295

From 1918 to 1923 104 cases of fracture of the patella due to accidents at work were reported to the National Insurance Office. Forty four of them were treated surgically. Only those subjected to operation are considered in this attempt to determine the results of treatment. These fractures require a long time to heal and there is considerable danger of permanent disability. The average time from the date of the accident until the resumption of full time work or settlement by the granting of compensation was 164 days. The average annuity granted the injured workmen was 21 per cent.

A clinical study was also made of the 21 surviving patients representing the operative material (23

Officers messes are generally entered for by contractors and therefore supervision of the kitchens is seldom effective. When an officers' mess is staffed by Army personnel the cook is an Indian, and although he may have been instructed in kitchen hygiene in the absence of proper supervision he will revert to unhygienic methods. Of course, all messes are subject to inspection, which in the case of officers' messes under war conditions, is irregular and often perfunctory. Foodstuffs for officers' messes are often purchased from local bazaars, and uncooked or cold food is frequently eaten. Unlike conditions in the other ranks where each man uses his own mess tin and other eating utensils communal eating utensils are used in the officers' messes, and these are seldom hygienically clean because boiling water is lacking for washing up purposes.

When travelling officers use the restaurants on trains and in stations extensively since they seldom carry rations and do not have the use of the station canteens. In off-duty hours also the officer is subjected to greater risk in that he eats away from his mess to a greater extent than other ranks. Hotels and clubs are mainly or exclusively used by him and the officer class on leave tends to eat more cold or uncooked dishes than other ranks during like periods.

An instance is cited of a hotel in South India much used by officers in transit. The kitchen of this hotel (unscreened) faced on an alley immediately contiguous to two open latrines of the Indian type.

Within a few days in the fall of 1944 7 cases of poliomyelitis developed here, 1 of which was apparently transmitted exclusively by fomites. Shortly before this outbreak 32 young officers arrived on leave at the hotel. Two of them had contracted poliomyelitis after suffering from diarrhea for several days. At a later date 24 of the remainder answered a questionnaire regarding their health during their stay in the hotel. All were fit on arrival, but after three or four days 3 of them felt ill with headache, 4 had diarrhea and a sore throat, and 2 had in addition, fever and pain in one leg. The symptoms were severe enough to confine them to bed for two or three days.

Although the author does not minimize the possibility of case-to-case transmission in the acute stage of poliomyelitis and the transmission by fomites he thinks it is important to consider food and eating utensils in the spread of the disease and recommends the following measures:

1. An improved standard of hygiene in all messes, elimination of contractors from messes, employment of British cooks whenever possible, and improved washing-up facilities.

2. A further warning to British troops of the risk which they run by the consumption of certain articles of uncooked food during the dry season.

3. The introduction of modern methods of kitchen hygiene in all civilian-controlled establishments, including railway restaurants, and a closer supervision of the Army kitchens by the medical officers.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Fariñas, P. L.: Retrograde Arteriography in the Study of the Abdominal Aorta and Iliac Arteries. *Surgery* 1945 18 344.

The author's original technique of retrograde arteriography whereby a rubber catheter is passed from the iliac artery to the desired level in the aorta was described in the 46th volume of the *American Journal of Roentgenology*. At present in view of the difficulties in obtaining rubber catheters he has been compelled to change his technique to the present retrograde abdominal aortography. With this technique the patient is given a barbiturate the night before the operation, and morphine hypodermically one hour before the injection whereupon the femoral artery is exposed by blunt dissection, under local anesthesia at the level of Scarpa's triangle, and punctured with a trocar 1.5 mm. in diameter. Through this trocar is now injected directly and in from 2½ to 3 seconds, 50 c.c. of a 70 per cent solution of diodrast after tourniquets have been placed at the roots of both lower extremities. In certain cases the Trendelenburg posture may be necessary. With a trocar 1.5 mm. in diameter and a constant pressure of 15 pounds which the author secures by a specially designed apparatus 25 c.c. of the shadow mixture are injected per second but the speed of injection is modified to suit the individual patient when necessary. The first plate is taken when 40 c.c. of the opaque substance have been injected, and a second immediately afterward, by means of a fast plate changer. When the injection is finished, the trocar is withdrawn, a stitch placed in the adventitia of the artery at the site of the puncture, and the wound closed.

In the study of the aorta and iliac arteries the most frequent lesion encountered has been atheroma, the characteristic picture of which was elongation and dilatation of the vessels and stenosis caused by lesions of the intima and by secondary calcification. Atheroma is usually found in old age and the lesions are generally seen all along the vessels, being more prominent in the aortic cone and in the iliac arteries.

In addition to the great accuracy with which this method of arteriography permits evaluation of changes in the arterial contour the presence of aneurysms and their degree of canalization it also depicts. In cases of complete obstruction of the aortic cone the characteristics of the consequent collateral circulation. According to the author this consists of anastomoses between the internal mammary and the epigastric arteries, and between the circumflex iliac and the lumbar arteries.

No accidents have been experienced with this method even in patients in very poor physical condition with advanced arterial lesions.

Pathological changes in the visceral branches of the abdominal aorta will be presented in another article.

JOHN W. BRIDGMAN, M.D.

Heifetz, C. J.: Traumatic Aneurysm of the First Portion of the Left Vertebral Artery. *Ann. Surg.* 1945 122 102.

A case report of a traumatic aneurysm of the left extracranial vertebral artery in which a complete cure resulted from an autogenous muscle transplant placed directly into the sac is presented with mention of the available literature on this subject.

Nearly all aneurysms of extracranial vertebral arteries result from traumatism, either gunfire or stabbing. The artery arises as the first branch of the ascending portion of the subclavian artery and ascends obliquely along the lateral margin of the longus coli to enter the foramen of the sixth cervical transverse process. The extraspinal portion is about 1½ inches long and lies beneath the thyrocervical trunk, carotid artery and internal jugular vein and the omohyoid and sternocleidomastoid muscle. Injuries to the vessel in the portion passing through the transverse processes are the most frequent.

The preoperative diagnosis is most difficult to make, frequent ligations of the common carotid artery having been performed by mistake. A pulsatile swelling in the posterolateral part of the neck following trauma is the usual history. Dissection is often difficult but arteriography by injecting into the sac may establish the origin of the swelling. No one surgeon has had sufficient experience to design a dependable approach for surgery. The singular course of the artery and its spacious anastomosis to the analogous vessels of the opposite side, and the connections with other branches and the circle of Willis, account for the inadequacy of proximal and distal ligation alone as treatment, and the difficulty of extirpation. Extirpation is at best hazardous and arduous. The method of incision and tamponade with gauze impregnated with astringents or antiseptics and the use of muscle transplants have been most often resorted to and have been most successful. With the latter method recanalization is said not to occur. Proliferative endarteritis obliterates the aneurysm. A variety of less radical procedures have been tried including injection, irritants and sclerosing media, electropuncture, and electrolysis. Endoneurysmorrhaphy was employed only in Spath's case.

This case report represents 1 of 15 on aneurysm of the extraspinal portion of the vertebral artery; a cure was obtained.

A twenty-seven year-old negro female appeared shortly after being stabbed in the neck over the sternocleidomastoid muscle. The instrument was a thin bladed pocket knife. Her blood pressure was 120/80 pulse 88 and temperature 98.6. Two at

tempts to control bleeding from an unlocated bleeding point were made, followed by packing (open) and a pressure dressing. Two days later it was possible to close the wound by suture. The patient was discharged on the third day to be readmitted on the eleventh because of a pulsating mass, steadily increasing in size since five days after she left the hospital. She was aware of a roaring in the ear and pounding in the neck, which kept her awake at night. The laceration was well healed. Loud systolic and diastolic bruits were heard and a loud systolic apical murmur was also heard. It was thought that the lesion was an arteriovenous aneurysm between the left common carotid artery and the internal jugular vein, or a sacular aneurysm of the common carotid artery. The laboratory studies contributed nothing.

The first attempt to isolate the sac and its tributaries was given up after two-and-one-half hours because of dense fibrous adhesions and the large size and extent of the lesion. The postoperative course was uneventful except that the aneurysm grew in size and the symptoms increased. The second operation was performed through a more extensive incision, including the old one in it. Accidental opening of the sac was controlled by insertion of the index finger which also made it possible to find that the aneurysm originated medially and posteriorly against the vertebral column. Ligation of the vertebral artery at the subclavian, which was also ligated proximal to this branch was done by extending the incision and removing part of the clavicle and sternum. Distal ligation was prevented by hemorrhage, therefore tamponade with live muscle transplants was done and the wound in the vessel was closed. The pulse and blood pressure was maintained by means of blood and fluids given during the procedure which required four hours and forty minutes. Convalescence was relatively uneventful, the aneurysm decreased in size and the only complaint was slight weakness and an ache in the arm.

JAY P. BARTLETT, M.D.

Bauer G.: Thrombosis following Leg Injuries. *Acta chir scand.*, 1944 90 9

A study of thrombosis at the Mariestad Hospital, Mariestad, Sweden shows that a little over a fourth of the cases of thrombosis occur following injuries to the leg. It may occur in as high as 32 per cent of patients who have suffered injuries of the legs. This frequency of thrombosis in leg injuries is doubtless partly due to the prolonged rest in bed but the author believes that the chief etiological factor is the retardation of the blood flow in the popliteal vein caused by swelling of the soft tissues around the knee which results in pressure on the popliteal vein. This theory is supported by the fact that the thrombosis practically always occurs in the injured leg.

Diagnosis in these cases is difficult as the symptoms of thrombosis may be confused with those caused by the original injury. Doubtless before the introduction of venography many cases were not

diagnosed and the whole series of post thrombotic sequelae such as swelling, induration, and leg ulcers occurred in cases in which they might have been prevented. In addition a patient with undiagnosed thrombosis may die suddenly from pulmonary embolism. Therefore, it is very important to make a diagnosis of beginning thrombosis, and the author believes it is justifiable if thrombosis is suspected, to cut the plaster bandage in order to make a thorough clinical and venographic examination. The risks from this procedure are much fewer than those from an undiagnosed and untreated thrombosis.

The best treatment for post traumatic thrombosis is preventive and consists of raising the foot of the bed and having the patient make alternate stretching and relaxing movements of the muscles of the leg, which he can do even with the leg in a cast. Bandages should not be allowed to constrict the region around the knee. Of the specific agents available for the treatment of thrombosis, heparin seems to be the best. As a rule heparin treatment is given for 5 or 6 days—3 doses of 150 mgm. each are given the first day then for a few days morning and evening doses of 100 mgm. and a midday dose of 100 mgm. are given. When temperature becomes normal the dose is reduced to two injections of 100 mgm. each and on the last day only one injection of 100 mgm. is given. However these patients can often not get up at the end of the heparin treatment on account of traction apparatus or casts therefore the heparin treatment may be continued with small doses to prevent recurrence of the thrombosis.

Thirty-three cases of post traumatic thrombosis have been treated with heparin at the Mariestad Hospital in the past 3 years. Only 1 patient died, a woman of 70 who had pulmonary embolism before the heparin had had time to take effect. In all of the other cases the disease did not spread beyond the area involved at the time treatment was begun. The use of heparin has reduced the death rate from pulmonary embolism at this hospital from 5 and 30 per cent to 3 per cent, and the probability of post-thrombotic after-effects has been practically abolished.

ANDREY G. MOROSAN, M.D.

Borgstrom, S.: Prothrombin Index after Operation. *Acta chir scand.* 1943 89 68.

Heretofore studies of the effect of operation on blood prothrombin have been chiefly in cases of obstructive jaundice, and it has been shown that there is a considerable decrease of prothrombin (sometimes amounting to as much as from 30 to 40 per cent) in these cases.

The author studied the effect of operation on the blood prothrombin level in 101 patients without icterus using Lehmann's micromodification of Quick's method of determining prothrombin. The cases were ones of chronic disease and the patients had been kept in the hospital for some time before operation, so that they were on the same diet and had had uniform treatment. Patients who had been given vitamin K or blood transfusions were ex-

clouded, as it has been shown that blood transfusion affects the prothrombin level for from 6 to 12 hours. No decrease in the prothrombin level was found on the day after operation and the amount of blood lost during operation did not make any difference. It has been claimed that a decrease of prothrombin is caused by the loss of blood. The loss of half a liter of blood by means of phlebotomy had no perceptible effect on the prothrombin index.

The anesthetics used by the author in these cases seemed to have a certain effect on the prothrombin level. There was no decrease after operations in which local or lumbar anesthesia was used but there was a small but definite decrease after operations under nitrous oxide and ether. The maximum decrease was on the fourth day after operation.

AUDREY G. MORGAN M.D.

BLOOD TRANSFUSION

Plaut, G., Barrow M. L. and Abbott, J. M. Results of Routine Investigation for the Rh Factor *Brit M J.*, 1945 2 273.

From routine examinations of blood information has been accumulated on the incidence and importance of the Rh factor. In the first series (3,944 cases), 84 per cent were Rh positive and 16 per cent were Rh negative. In a second series (2,473 cases) in which further subdivisions of the Rh factor were made, 83.3 per cent were Rh-positive, 14.9 per cent were Rh-negative, 1 per cent were Rh- and 0.7 per cent were Rh.

Of 136 women with infants presenting either a history or serological findings suggesting hemolytic anemia, 120 (88.2 per cent) were Rh-negative. The red cells of 55 affected babies with Rh negative mothers were available for examination in 53 they were Rh positive and in 2 they belonged to the sub-group Rh-negative. Anti-Rh agglutinins were found in the serum of 94 (79.6%) of the 120 Rh negative women. In the remainder no anti-Rh agglutinins could be found even though tests were made under varying circumstances during and after pregnancy.

The first pregnancy of 80 of the 120 Rh-negative mothers ended with a child normal at birth and during infancy. In 27 cases the child was suffering from hemolytic disease or was still-born in 5 the pregnancy ended in a miscarriage and in 8 the child died from unknown causes or from causes other than hemolytic disease of the newborn. Of the 80 normal first children, 33 were Rh-positive, 5 were Rh negative and 42 were not tested.

Reactions were reported in 48 patients after the transfusion of blood of the compatible ABO type. 18 occurred in Rh-positive patients and 30 in Rh-negative patients. Of the 30 Rh negative patients included, 2 had previous transfusions with known Rh-positive blood without any reactions. The transfusion of Rh-negative individuals with Rh-positive blood is a not uncommon cause of relatively mild reactions and may result in more severe reactions.

LUCIAN J. FROMMELT M.D.

Volkert, M. and Piper, J.: Heparin Content of the Blood in Clinical Thrombosis. *Acta chir scand.*, 1943 89 417.

Experiments on rabbits have shown that certain operations on the veins might produce an increase in the heparin content of the blood. In the authors' experience, however, this did not occur unless factors which cause coagulation, such as sutures of thick silk through one or more of the veins, were used during the operation.

It was therefore believed worth while to make a clinical study to determine whether such increase in heparin content could be brought about by operation in man. The heparin content was measured by determination of the antithrombin content of the blood.

Details concerning the results obtained in 33 cases are shown in a series of tables. From these it is evident that the heparin content of the blood in man increases only in very serious and dangerous thrombotic conditions such as for example relapsing infarction of the lungs in which after a certain latent period, there was an increase of the heparin content to double its normal amount.

It would seem, therefore, that an increase in heparin content of the blood has a certain value in prognosis but the available material is insufficient to permit of final conclusions on this subject. Since the human body apparently tries in certain cases to counteract dangerous thrombosis by increased production of heparin, it is possible that heparin medication may be indicated to support this defensive action.

AUDREY G. MORGAN M.D.

Reich, C., Yahr M.D., Eggers, C. and Lipkin R.: Dicumarol in the Prevention of Postoperative Thrombosis and Pulmonary Embolism. *Surg* 1945 18 238.

During the period from October 1943 to July 1944, in an effort to further evaluate the use of dicumarol, the authors subjected a series of surgical patients (103 cases) to a prophylactic course of the drug with the thought of preventing postoperative thrombosis and pulmonary embolism. During this same period the drug was used in the treatment of cases of venous thrombosis (33 cases) and pulmonary embolism (9 cases) which arose in the surgical services.

Since the statistics show that this condition does not begin until approximately the sixth or seventh postoperative day, it was believed best to start the drug on the third to the fourth postoperative day. In this way the prothrombin time was not prolonged at the time of operation and a few days were permitted to elapse postoperatively in order that healing might begin. That this time, namely the third or fourth postoperative day, was the most opportune day to administer the drug was shown by the fact that neither thrombotic phenomena nor postoperative bleeding were found.

Before administration is started, a prothrombin determination is done to find the patient's normal blood level. After this has been established, 300

mgm. of dicumarol are given then on the following day a prothrombin level is done again and unless it is markedly prolonged 100 mgm. of the drug are given at this time. The object is to prolong the prothrombin time to twice its normal value. In other words if the normal time is from 17 to 20 seconds the therapeutic range would be about 34 to 40 seconds. Subsequent doses must be adjusted individually. In many cases the prothrombin time is prolonged rapidly and prothrombin determination on the third day shows that the patient is already in the therapeutic range, then it is best not to give any drug on that day and to see what the prothrombin level is on the fourth day. If it is still in the therapeutic range, no drug is given on that day either. On the other hand, if the prothrombin time is rapidly becoming shorter another 100 mgm. of dicumarol are given. Other patients will be found who do not reach the therapeutic range with the first 300 and 200 mgm. of dicumarol. In these instances 100 mgm. administered on the third day and prothrombin observation is done daily after that. Sometimes even 50 mgm. are enough.

If bleeding should occur at any time during the period of treatment a transfusion of fresh citrated blood, plus 60 mgm. of water-soluble vitamin K intravenously will raise the prothrombin level promptly.

Salicylates notably aspirin, should not be given at the same time that dicumarol is being used.

Directions for the preparation of thromboplastin (rabbit's lungs) for the prothrombin test, and for the carrying out of the test are given in the original article.

From the results of the prophylactic experiments, wherein no thrombotic phenomena in 101 surgical operations were experienced, and the results of treatment of venous thrombosis and pulmonary embolism arising during the period of these experiments in 591 surgical and obstetric procedures, wherein again, dicumarol, carefully administered, resulted in uniformly favorable results (the thrombophlebitis clearing up promptly and none of the pulmonary emboli causing fatality) the authors believe that dicumarol is a safe means for preventing postoperative venous thrombosis and pulmonary embolism.

Whether this synthetic preparation should be used routinely is still a matter of discussion; nevertheless the authors are convinced that dicumarol should be given in all cases in which thrombotic complications are likely to arise including extensive pelvic operations, operations for abdominal malignancy and operations on individuals who have previously shown a tendency to thrombosis. Naturally it is the drug of choice when these conditions have already developed since it is cheaper and more readily available than heparin, and may be given by mouth. However in cases of acute pulmonary embolism it is proper to administer heparin by vein (see original article for details of technique), and start dicumarol by mouth at the same time. This should be done because dicumarol has a latent period of from 24 to 48 hours

and it is important to have the coagulation mechanism altered by the heparin until dicumarol takes effect.

Tables list the average total dosages employed by the authors for each type of operation, and for each type of case wherein thrombotic or embolic conditions have arisen, these dosages ranging from 700 to 2 100 mgm. of dicumarol. The average number of days in the corresponding therapeutic range vary from 4 to 25 days.

JOHN W. BARON, M.D.

Sharpey-Schafer E. P.: Transfusion and the Anemic Heart. *Lancet*, Lond. 1945 49 ppd.

Blood transfusion may be an essential life-saving procedure in severe anemia. The main purpose of such transfusions is to raise the oxygen-carrying power of the arterial blood by increasing the concentration of hemoglobin, and although the exact time is difficult to assess clinical evidence suggests that it is often a matter of days before improvement becomes evident. Meanwhile there is a period of risk and anxiety for it is well known that patients with severe anemia stand transfusion badly. Many of these so-called "transfusion reactions" appear to be circulatory in origin, since the clinical signs and, in fatal cases the postmortem findings show pulmonary edema. There is good evidence that the heart is not normal in severe anemia: anginal symptoms indicate myocardial ischemia, the size of the heart in roentgenogram and the weight of the heart, postmortem may be increased and electrocardiographic changes present.

The author reports the effects of transfusion on circulatory dynamics which have been studied by cardiac catheterization, a method allowing serial measurement of the output of the heart, and pressure in the right auricle.

From his observations, the author concludes that in severe anemia the blood volume is reduced, and that the right auricular pressure, cardiac output, and percentage utilization of available arterial oxygen are decreased.

Transfusion raises the right auricular pressure and in normal subjects increases cardiac output, but in severe anemia cardiac output may fall. Acute pulmonary edema follows in some cases and the blood pressure may rise.

The author suggests that the heart in severe anemia behaves like Starling's overloaded heart preparation. Starling showed that, if the rate was kept constant, raising the venous filling pressure caused a parallel rise in cardiac output until a point was reached at which a further rise in pressure caused no further rise in cardiac output, and at still higher venous pressures a fall in cardiac output resulted. In severe anemia the heart seems to respond as in this last phase, so that when the venous filling pressure is further raised by transfusion, the result is a falling cardiac output.

The purpose of transfusion in severe anemia is long term benefit from increased arterial oxygen content, while venous filling pressure is raised as

little as possible hence the small slow concentrated transfusion. Other suggestions include the propped up cardiac posture and clinical observation of venous pressure.

JOSEPH K. NARAT M.D.

Frieh, A. W. Hemolytic Transfusion Reactions Due to the Rh Factor. Report of 2 Cases. *Am J M Sc* 1945 210 184.

In 3 patients severe reactions following multiple transfusions were found to be due to the Rh factor. The first was a 24 year-old white male with Hodgkin's disease, and Group O and Rh negative blood who received 4 transfusions within 18 days without presenting any reactions. Four days later an administration of washed red blood cells resulted in hives, dyspnea and icterus. During the following 20 days, the patient received 4 transfusions of citrated blood and 2 red cell infusions each followed by chills and fever. One week following the last transfusion a warm agglutinin was detected and tested against 17 known bloods of all groups. The patient's serum proved to agglutinate 69 per cent of the bloods tested, among them being 5 Rh negative bloods. This finding is known to be characteristic for serum designated by Weiner, Sonn, and Belkin as anti-Rh₁. The second patient, a 22 year-old white male with aplastic anemia, received 15 transfusions during a period of 10 months at least 5 of which consisted of Rh-positive blood. Four months later transfusions had to be resumed but the patient showed severe reactions to small quantities of blood which proved to be Rh-positive. The patient was found to be Rh negative and therefore, received subsequently only negative donor's blood (13 transfusions). Subsequently due to lack of Rh negative donors, a transfusion of Rh-positive blood was given. This was followed by weakness, nausea, vomiting, icterus, hematuria and hemoglobinuria. The patient's condition improved after the administration of fluid. Examination of the patient's blood did not reveal any Rh-positive cells but his serum was proved to contain "blocking antibodies" as described by Wiener and Race. These inhibiting antibodies are nonagglutinating and therefore, cannot be detected by direct agglutination tests. They have to be demonstrated by the inhibition exerted by the patient's serum on the reaction between known Rh-positive cells and a known anti Rh serum.

ARTHUR J. LESSER, M.D.

RETICULOENDOTHELIAL SYSTEM

Borne, J. L., Kirkpatrick, H. J. R., Lederer H. and Lays, D. G.: Familial Crises in Congenital Hemolytic Disease. *Lancet Lond* 1945 249 33

Acute hemolytic crises form a well-recognized part of the symptomatology of familial acholuric jaundice, but the literature contains few records of these crises arising almost at the same time in several members of the same family. The authors report an instance in which 3 sons and daughters and the mother in a family of 7 mem-

bers developed acute hemolytic crises of great severity within a period of a few days of each other. At almost the same time a cousin of these children was affected by a similar crisis.

The authors made a very thorough study of these cases but no explanation could be found for their simultaneous appearance. DAVID H. LYNN M.D.

James, D. F., and Evans, L. R. Splenectomy for Acquired Hemolytic Jaundice in the Aged. *N England J M.*, 1945 233 143.

The authors present the case of a seventy year-old woman who, four months prior to her admission to the hospital first experienced malaise, increased weakness, fatigability, palpitation and shortness of breath on exertion. On admission the patient appeared to be severely ill as evidenced by prostration, tachycardia, pallor and a lemon yellow skin. The tongue was smooth and pale. The blood pressure was 130/40. There was present a loud blowing apical systolic murmur. The liver and spleen were barely palpable.

Of the significant laboratory data the red cell count was 870,000 with 17 per cent reticulocytes. The white cell count was 17,500 and the differential count was normal. The hemoglobin was 32 per cent. The icteric index was 20 and by the Sanford method of erythrocyte fragility determination, hemolysis began at n.44 per cent saline solution and was complete at n.34 per cent, both values being within the limits of normal, and equivalent to those of a normal control blood tested at the same time. When however enough plasma had been removed from the blood of the patient to make the hematocrit reading normal—that is 40—and the fragility was again tested by the Sanford method it began at n.50 per cent and was complete at 0.40 per cent, values definitely indicative of greater fragility than normal.

In order to check the findings of these naked-eye tests the photoelectric method of Hinnter was used. The blood with a hematocrit level of 17 was tested. When fragility was determined by this method hemolysis began at 0.60 per cent saline and was complete at 0.36 per cent, whereas in the normal control it began at n.48 per cent and was complete at n.34 per cent. The blood smears showed anisocytosis, macrocytes, polychromatophilia, stippling and a few erythroblasts and normoblasts. No spherocytes were seen. Routine x rays were negative. Gastric aspiration revealed free hydrochloric acid. Liver extract and multiple whole blood transfusions gave little improvement and therefore x ray therapy was administered on the supposition that the etiological process might be neoplastic in nature. This however resulted in a decrease of the white count and was therefore discontinued. Meanwhile the patient developed a severe pain in the right upper quadrant which was interpreted as due to obstruction of the cystic duct.

Because of these findings and the failure of the patient to respond to the vigorous transfusion therapy she was transferred to surgery for splenec-

tomy. At operation the gall bladder was tense and distended but no stones could be palpated. It was not removed. The spleen was removed and the pathological report was consistent with that of a hemolytic anemia. She was discharged on the twenty-second postoperative day remarkably improved, with a red-cell count of 4,300,000 and 11.5 gm. of hemoglobin. The icteric index was 14. Although abnormal red-cell fragility persisted she was entirely well and more vigorous than she had been in the previous ten years.

The authors point out that an erroneous result in red-cell fragility was obtained in the presence of marked anemia. They suggest that a more accurate test, such as Hunter's, replace the more widely used Sanford test in these cases.

The diagnosis of congenital and acquired hemolytic jaundice is discussed and the authors state that a case of hemolytic jaundice should not be termed congenital until evidence is found in the family of characteristic symptomatology or of microspherocytosis or increased red-cell fragility. Dameshek denied that increased saline fragility was pathognomonic of congenital icterus but believed it might be regarded as a regeneration phenomenon or as a sign of the action of toxic or hemolytic forces on the red cells in the circulation. Ham and Castle suggested that erythroblast in the spleen and other organs would account for increased fragility. These

observations demonstrate the difficulty in determining the fundamental nature of a hemolytic jaundice from fragility studies alone.

In the authors' case the most cogent points that argued against the congenital type were a sudden appearance of severe hemolytic anemia in old age and the absence of a familial history and the pathological picture of the spleen was not characteristic of congenital hemolytic jaundice. Therefore the diagnosis made was relatively acute hemolytic anemia of the acquired variety.

A study of the literature revealed reports of 14 patients in whom the onset of hemolytic jaundice occurred at or beyond the age of fifty, only 1 of these patients was beyond the age of seventy. Five patients showed definite improvement after splenectomy. In the other 9 patients splenectomy was ineffective.

The cases reviewed from the literature as well as the one reported by the authors demonstrate that splenectomy may save the lives of elderly patients with acquired hemolytic jaundice. Although good results following splenectomy are more likely to occur in patients with increased erythrocyte fragility, spherocytosis and a spleen typical of congenital hemolytic jaundice, splenectomy is sometimes of value in patients whose clinical picture lacks one or more of these characteristics.

DOUGLAS E. MCCROW, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Schwartz, L., and Mason H S: Cleansing of Oil Covered Skin and Burns. *Arch Surg* 1945 51 55

In this investigation of the cleansing of oil-covered skin and burns 165 surface active agents commercially available, were systematically studied. Some 350 mixtures of single surface-active agents or surface-active agents in combination with both light and heavy liquid petrolatum (purified mineral oil) were the subjects of approximately 700 tests of comparative activity in removing heavy fuel oil and tar from the skin. The test oils employed were heavy and light fuel oils.

Three mixtures of surface-active agents were found capable of completely removing heavy fuel oil, without ostensible mechanical action in the course of 3 fifteen minute applications on surgical gauze, but were also found to have poor detergency. Diocyl sodium sulfosuccinate in 10 per cent light liquid petrolatum solution had good detergency and high activity as an oil remover in dressing form.

SAMUEL KADAN M D

Kelly R. P. Rosati L. M. and Murray R. A.: Traumatic Osteomyelitis: the Use of Skin Grafts. *Ann. Surg* 1945 122 1

A technique for the skin grafting of osteomyelitic cavities following saucerization was employed in approximately 100 osteomyelitic wounds over a two-year period at an Army General Hospital. Beneficial results were obtained in the majority of cases.

First every effort is made to improve the patient's general condition. Saucerization is then carried out in a manner analogous to the débridement of a fresh wound. In addition, the wound topography must approach a saucer shape, to attain this one should not hesitate to sacrifice bone, provided that in so doing the surgically created bone weakness does not exceed the pre-existing weakest link. A complete removal en bloc of all unhealthy tissue and of all foreign bodies is desired. Any remaining tissue which appears to be of low vitality should be removed. Finally, any tendon denuded of its sheath or any exposed ligament which will not contribute to the anticipated function of its joint, is excised. If such a structure is vital, an effort is made to cover it with a flap of local healthy skin.

The postsaucerization dressing consists of a layer of fine mesh gauze in direct contact with the wound. Over this is packed a suitable mass of mechanic's waste and then an Ace bandage is applied with as much pressure as the wound can stand without embarrassment of the circulation. A thick layer of sheet wadding is placed over the Ace bandage and immobilization is done with plaster.

Skin grafting is usually done four days after saucerization. Uniformly healthy granulations, however thin which are visible after four days of pressure dressing are an index of a healthy wound likely to respond favorably to grafting. Grafts are cut with the Padgett dermatome. When they are applied to the wound cavity wrinkling must be avoided as well as tension. When placing of the grafts is necessary untied running sutures are placed with one end left long. These can be easily withdrawn when the graft has become firmly adherent to its bed. The margins of the graft are sutured to the skin edges with nonabsorbable material. With two exceptions the dressing is essentially the same as that after saucerization. Bono-acid gauze is preferred for contact with the graft and somewhat less pressure is applied. Better results have been obtained when the dressing is irrigated either with weak acid solution or with 1,250 penicillin. The dressings are removed in four to six days according to the amount of exudate present and moist dressings with boric acid or penicillin are continued until complete epithelization has occurred.

In evaluating the results of 47 skin-grafting procedures in 43 patients it was considered that they were poor in only 24 per cent. In the remaining 76 per cent a satisfactory take with progressive healing was obtained. In view of the beneficial results in the majority of cases it is believed that the use of skin grafting in traumatic osteomyelitis has failed to receive the general adoption its effectiveness warrants.

JOSEPH J. McDONALD M.D.

Burke J. and Jacobs, T. T.: Trans thoracic Operative Approach for Traumatic Lesions of the Spleen. *Arch Surg* 1945 51 28.

Splenic injuries are not uncommon among battle casualties and are usually associated with other intra-abdominal or intrathoracic injuries. Today the consensus is entirely in favor of splenectomy for splenic injury. The preferable incision for splenectomy in these circumstances depends to some extent on concomitant injuries.

While statistics for the authors theater of operations are not available at present observation of patients admitted from forward hospitals and conversation with other surgeons give the impression that the majority of splenectomies are performed through a vertical left rectus incision on the left side with or without a transverse extension. A few cases have been observed in which a transverse incision has been used. The authors have utilized the trans thoracic route.

At first sight it may seem that, although splenectomy may be feasible through the trans thoracic approach exploration of the peritoneal cavity will be at best, limited. Burke and Jacobs have found that it has been possible to explore the entire small

intestine the transverse and descending portions of the colon the stomach and the proximal portion of the duodenum although in 1 case a perforation high on the lesser curvature could not be visualized.

The operation has been performed with the patient under anesthesia induced with ether and oxygen administered endotracheally which permits re-expansion of the lung before closure of the wound. The chest is opened by an anterolateral incision either through the eighth interspace or through the bed of the eighth or the ninth rib. Resection of the rib seems to give a little better exposure although with the Filck rib spreader adequate exposure is obtained by either method. Phrenicostasis is not necessary to produce a flaccid diaphragm. The diaphragm is incised radially and the spleen is located and brought into the operative field without difficulty. Adhesions may be removed by sharp dissection under complete visual control. The pedicle may be ligated en masse or by separate dissection of the vessels, according to the desire of the operator. Any desired further exploration is then performed. The case with which all manipulations about the spleen may be carried out is a pleasant surprise and the splenectomy itself is much easier than through any abdominal incision. The diaphragm is closed with two rows of interrupted silk or fine chrome sutures. Whether or not the pleural cavity should be drained routinely has not been determined.

It cannot be denied that in theory at least there are dangers in connection with this approach which are not associated with an abdominal incision. The possibility of empyema must be kept in mind as well as the possibility of late herniation through the sutured diaphragm. These complications have not occurred in the reported cases nor have the authors heard of their occurrence in the cases of other surgeons in their theater of war. Three cases are reported.

BENJAMIN GOLDMAN M.D.

Maier R. L.: The Present Status of the Injection Treatment of Hernia. *Ann. Surg.* 945 22 85.

The revival of interest in the injection treatment of hernia so apparent ten years ago in many parts of the country seems to have subsided to a great degree. The author states that in the last five years he has seen no reports from responsible clinics advocating this form of treatment.

In the light of his experience in operating on 66 patients he has come to the definite conclusion that injection treatment has no place in the treatment of hernia and its use should be condemned. In 1934 after being taught injection methods by one of its ardent protagonists he treated a group of 66 patients with 93 hernias. In 1937 some 36 of these patients had been followed up and only 11 showed no definite evidence of recurrence but 9 of these were still wearing trusses. In a later check-up of these 11 cases none was found to be cured.

Because of recent experiences in treating patients by surgical repair following injection treatment, the

author believes that the injection method does not cure hernia, but actually complicates the conditions to such a degree that any subsequent attempts at surgical repair lessen the patient's chance of a cure. Marked fibroplasia, loss of tissue resiliency, semi-cartilaginous rings of tissue and cases of strangulation are but a few of the complications seen following injection treatment.

JAY P. BARTLETT M.D.

Maier G. B.: Use of Whole-Skin Grafts as a Substituta for Fascial Sutures in the Treatment of Hernias. Preliminary Report. *Am. J. Surg.* 1045 69 332.

Brigadier Edwards recently presented the modern views on the treatment of inguinal hernia in the *British Journal of Surgery*. He believes the Bassini operation is inefficient and harmful, and that it should be abandoned. In place of it he suggests a physiological repair with high ligation of the sac combined with repair of the torn or weakened transversalis fascia or a plastic repair with fascial sutures to narrow the internal ring and to strengthen the weakened posterior wall of the inguinal triangle. He believes improvement in results will come not from the evolution of new ideas but from more careful technique, better pre and postoperative care and the election of the most suitable method of repair for each case.

This article is a preliminary report suggesting that the use of whole-skin grafts inlaid under tension in such a way as to protect the posterior wall of the inguinal canal and narrow the internal ring may be superior to fascia in most cases.

Fascial sutures were first suggested by McArthur in 1901 when he cut strips from the aponeurosis of the external oblique and sutured with them. His methods since that time have not been extensively accepted, and few surgeons routinely employ this method. Kirschner first used fascia lata in 1910, and Gallie and LeMessurier advanced his work by using special needles. They showed that fascia excited no inflammatory reaction survived many years united with the tissue in which it was imbedded, and did not stretch under pressure as does ordinary scar tissue. In a few weeks the fascial strips become surrounded by a film of vascular areolar tissue from which septa of similar tissue penetrate between the folds and into adjacent structures to effect a firm union—a plaque of fibrous tissue. By 3 weeks time the fibrous strip on cross section closely resembles normal tendon.

Edwards gives as indications for fascial repairs (1) all recurrent hernias of any type (2) all primary direct inguinal hernias (3) all primary oblique inguinal hernias with muscle atrophy and weakness of the rings and posterior walls (4) all funicular or "saddle bag" types of hernia (5) the final stage in the Mayo repair of umbilical hernia and (6) the final stage in repair of large ventral or incisional hernias.

Since fascia is reserved for cases most likely to recur the evaluation of recurrence is very difficult.

For indirect hernias it averages 12 per cent. Other writers give figures between 5 and 50 per cent for indirect and between 7 and 42 per cent for direct hernias. If fascia has been used the recurrences are between 5 and 9 per cent for indirect hernias and between 7 and 9 per cent for direct. Therefore it is clear that even in a less favorable type of case fascia reduces the recurrence rate.

Fascia has the following disadvantages:

1. The McArthur method does not give enough fascia to fulfill the requirements of an ordinary case, and it is applicable mainly to the inguinal type of hernia.

2. The Gallie technique involves an extensive thigh wound or the use of a fasciotome. In either case, there may be intractable pain referred to the thigh and hip joint, and the possibility of an obvious muscle hernia. The etiology of this pain is obscure, but about 25 per cent of the cases are involved.

3. Infection of the abdominal wound more commonly follows this type of hernioplasty (7.9% of cases with autogenous fascia and 12.1% of those with or fascia).

4. There is increased liability to develop postoperative chest complications in these cases partly because of increased operative time and partly because of the decreased vital capacity and muscle spasm associated with a plastic repair.

5. Fascia unites to fascia under considerable tension, but potential gaps occur between fascia strands and all strands do not unite with one another. Recurrences usually occur between strands forming a direct sac (usually close to the medial aspect of the canal).

6. The needle used in the Gallie method is large and apt to traumatize the inguinal ligament or damage the femoral vein.

7. There is a substantial recurrence rate—the figures may be considerably higher in the hands of many surgeons.

Much research has been carried out on the use of sterilized dead fascia which overcomes many of these disadvantages. However this use has not become very popular as yet and does not seem to have affected the recurrence rate.

Rehn and Loewe advocated a method known as "cutis" graft for the repair of anatomical defects in postoperative hernias. This graft was made of all elements of skin except epidermis and was elastic, inherently active, and composed of a rich network of connective tissue fibers. These factors permit after transplantation and stimulated by the tension under which the graft is sutured it rapidly undergoes metaplasia into stout connective tissue. It has been reported that regeneration is more complete and more rapid than when fascia is used.

Wihlein, operating on 2 patients who had submitted to cutis grafts 4 years before found complete metamorphosis of the transplants. The grafts represented normal connective tissue and no hair follicles or glandular tissue could be identified. There was no evidence of cyst formation.

Rehn used this method in 104 operations with 15 cases of wound sepsis and 6 poor late results. Cannaday declares these grafts are superior to fascia and that the grafts heal firmly and promptly and are easily obtainable. He used these grafts for 37 operations (27 hernias) with only 2 cases showing mild sepsis and 2 small hematomas.

Eitner and Peer and Paddock found that it is impossible to remove every bit of the epidermis; the splices of hair follicles and the sweat glands remaining. After implantation these disappear and the grafts fuse with their surroundings through a mechanism of inflammation and aseptic wound healing.

Many investigators have shown that epidermis alone implanted in the skin will produce smooth walled cysts which contain no dermal elements. Peer and Paddock and Rehn and Cannaday and his associates have done work showing that the method is entirely safe and the risk of epidermoid cyst formation is remote. It is important that the grafts be placed under tension since metaplasia is then much more rapid and complete.

Rehn originally denuded an area of the thigh of epidermis with a Thiersch razor and cut the cutis graft from this. The edges of the resulting wound were devoid of epithelium and healed slowly when closed. The author wondered if it really was necessary to remove the epidermis and investigated the use of whole-skin grafts sutured under tension in guinea pigs and rabbits. At the same time he applied the operation to a considerable number of hernias in which fascia would have been used.

In 1938 the author first used a whole-skin graft in repairing a large ventral hernia. The graft measured 4 by 5 inches and was sutured to the anterior aspects of both rectus sheaths and the medial aponeurotic expansions of the external oblique. The repair was firm and satisfactory 18 months later with no recurrence or other complication. He later used the same method (from 1938 to 1943) on 7 large ventral, 3 umbilical hernias, and 1 epigastric hernia without complication. Follow-ups have been complicated by the war but immediate results were very encouraging and the author began applying the same methods to the repair of inguinal hernias.

Experimentally the author used whole skin grafts under tension to close fascia defects in rabbits. The first group with hair left to a length of 5 mm when examined five months later showed disappearance of the sebaceous glands, epidermis and hair follicles. The hairs were surrounded by a massive foreign body reaction and this in turn was encapsulated by a firm fibrous stroma. The degree of metaplasia was striking and microscopically the edge of the graft was determined with difficulty. Under the microscope a few atrophic sweat glands and dermal papillae were seen. The dermis showed a dense fibrous tissue infiltration and high vascularity.

A second group with the hair shaved off, showed similar findings with a less intense foreign body reaction. No trace of epidermoid cyst formation was

seen. Instead, the epidermis was being desquamated and the cells and debris were being removed by phagocytes.

The author explored an inguinal canal in a human being into which a whole skin graft had been sutured for a large direct hernia three months before. The graft was firmly attached to Poupart's ligament the medial aponeurotic aspect of the internal oblique, and the insertion of the rectus sheath in the pubis. The edges of the graft could not be ascertained with certainty and the appearance closely resembled a normal inguinal canal. The dense fibrous tissue and deformity of anatomy seen in the recurrent fascial repairs were absent. The graft microscopically showed highly vascular connective tissue without dermal or epidermal elements. No hair remnants were found. Microscopically no evidence of cyst formation was seen—only a number of giant cells.

The author believes that no contraindication to the use of these grafts in human beings has been found to date and he used them in a series of 119 inguinal hernias of all types 6 umbilical hernias 10 ventral, 1 femoral hernia and 1 epigastric. In this group there were 2 cases of mild sepsis 1 case of scrotal hematoma, and 12 cases of mild postoperative bronchitis. Late postoperative complications have not been seen, and as yet it is too soon to study recurrency figures. The author prepares the skin (for three days) by careful shaving and washing with ether soap and warm water for 10 minutes. Spirit compresses and a sterile bandage are then applied. He suggests a gas-oxygen-ether or spinal anesthesia to give maximum muscle relaxation so the graft can be placed under maximum tension. The skin for the graft is encompassed on the original incision and measures about 8 by 1. It is prepared by removing the subcutaneous fat. The ends are cut off, and the graft is split for a distance of $\frac{3}{4}$ inch down one end. The graft is placed in the inguinal canal, and the apex of the V is brought around the cord. Three 30-day chronic sutures are used to hold the medial margin of the graft to the lower aspect of the rectus sheath, the fascia over the symphysis and the medial edge of Poupart's ligament. The graft is then sutured to the shelving edge of Poupart's ligament and the aponeurotic medial edge of the internal oblique with sutures $\frac{3}{4}$ inch apart. Care is taken that the graft be sutured under great tension. The outer pedicles of the graft are then joined laterally to the internal ring and outside of the emerging cord.

The patients are allowed up on the twentieth day since fascia does not heal firmly in less than three weeks. The same principles can be adopted for direct hernias and whole skin grafts can be used for final re-enforcements for umbilical, ventral, and epigastric hernias. ROBERT R. BRIDGEMAN M.D.

Green R. W. Levenson, S. M., and Lund, C. G.: Nylon Backing for Dermatome Grafts. *N Eng J Med* 1945 233 268.

In the use of the drum technique of skin grafting, as described by Padgett in his book on skin grafting

(Springfield Charles C. Thomas, 1945) some surgeons have been using a backing on the drum, such as plex film (Webster) and cellophane (Evans). The author suggests a fine-gauge nylon cloth for the same purpose. Before the graft is cut the drum is coated with dermatome cement and the backing is cemented to the drum as smoothly as possible. New coats of cement are then applied to the backing and to the donor site and the graft is cut as described by Padgett. The graft with its back is removed from the drum and placed on the recipient site. No sutures are needed to maintain the graft at its original size and tension, it being merely maintained in place by even elastic pressure provided by a suitable pressure dressing with or without external splinting.

The advantages claimed by the author for his nylon-cloth backing are (1) that nylon can be sterilized as easily as any textile and is physically unchanged after sterilization and (2) that grafts backed with nylon conform better to irregular surfaces than do those backed with cellophane, yet in spite of the relative limpness of the nylon before it is attached to the skin it prevents contraction of the graft as well as cellophane or sutures.

A case history is given and 6 figures to illustrate the method and the results of treatment.

JOHN W. BRIDGEMAN, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Harkins, H. N., Cope O., Evans, E. I., Phillips, R. A., and Richards, D. W., Jr.: Therapy of Burns. *J Am Med Ass* 1945 138 475.

This memorandum is released by authorization of the National Research Council and Office of Scientific Research and Development. Chemotherapy with penicillin and sulfonamides is not within the scope of the present discussion.

Following burns, there is loss of extracellular fluid salts and plasma. In patients with minor burns involving less than 10 per cent of the body surface it is generally agreed that restitution takes place by the ingestion of fluids and food, according to the desires of the patient. However in patients with severe second-degree or third-degree burns of at least one of the following areas (face and neck, dorsal or ventral surface of chest, dorsal or ventral surface of abdomen, upper extremity and dorsal or ventral surface of lower extremity) parenteral fluid administration is necessary.

Three dangerous phases are observed in severe, and inadequately treated, burns.

1. Shock may be present for as long as 48 hours after the burn but clinical signs may not be obvious since generalized vasoconstriction may keep the blood pressure at satisfactory levels even though cardiac output is greatly diminished. Therefore, vigorous fluid therapy is essential during the first 3 days of every case of severe burn.

2. The period of toxemia (from 48 to 128 hours occasionally up to the third week) is manifested by

fever jaundice, anuria stupor delirium and circulatory collapse

3. The third phase is defined as the period of burn anemia and hypoproteinemia

Fluid therapy should be directed toward rapid replacement of acute deficits and the maintenance of daily needs. In severe burns involving from 30 to 40 per cent of the body surface from 8 000 to 15 000 c.c. of fluid in a period of 24 hours may be necessary. The dosage of plasma can be estimated by giving 100 c.c. for each point of hematocrit exceeding the normal of 45 (or for each 100,000 the red blood count exceeds 5,000,000) or 50 c.c. of plasma for each per cent of the body surface that is involved by a deep burn.

Iso-osmotic human albumin solution is a satisfactory substitute for blood plasma.

In patients with hematocrit readings below 60 about 500 c.c. of blood should be given with every 1,000 c.c. of plasma.

An attempt should be made to maintain the urinary output above 100 c.c. per hour for the first 48-hour period; however an initial period of anuria lasting from 4 to 5 hours is not uncommon.

If the plasma carbon dioxide is less than 55 vol umes per cent 40 c.c. of 4 per cent sodium bicarbonate intravenously or 125 c.c. of 1.3 per cent sodium bicarbonate or 185 c.c. of 1.75 per cent sodium lactate should be given for each point of carbon dioxide below 55.

After a period of 48 hours excessive fluid administration should be avoided because of the danger of circulatory embarrassment and pulmonary edema. The aim then, is to maintain water and salt balance and to raise the hemoglobin to 85 per cent and the protein blood level above 6 gm. per 100 c.c. Blood transfusions and daily intravenous administration of amino acids in amounts up to from 100 to 150 gm in a 10 per cent solution, are indicated.

Oral therapy also is very important and should consist of from 3 000 to 4,000 c.c. of fluid in order to insure 1 500 c.c. of urine daily. Ten grams of sodium chloride are given daily, and a diet of from 3,000 to 5,000 calories composed of from 200 to 300 gm. of proteins and if tolerated 100 to 300 gm. of amino acids along with large doses of carbohydrates vitamins and iron.

ARTHUR J. LASKER, M.D.

Flemming, C. W. The Treatment of Burns; A Plan for Simplicity. *Brit M J* 1945 2 314.

General Mitchiner's quotation, "It can be said truthfully that the treatment of burns has returned to chaos" forms the subject of the author's article.

In the present state of our knowledge the treatment of burns must be to some extent empirical, because the pathological processes which make the patient ill or cause his death are as yet not fully understood. However by careful observation of those signs and symptoms which are comprehensible a high standard of treatment can be achieved function can be preserved and lives saved. There is no single all-embracing universally applicable

treatment for burns and never will be. The surgeon must vary his detailed technique from case to case as in any other branch of surgery.

Severely burned patients travel badly until their general condition is stabilized which usually takes from 4 to 10 days.

From the clinician's point of view burns are of two degrees slight and severe. Slight burns are those in which there is no detectable disturbance severe burns are those in which the general treatment of the patient is more urgent than the local treatment of the burn.

There are three types of local dressings available for the treatment of slight burns (1) wet dressings of saline solution or antiseptic which should be changed at intervals (2) occlusive dressings of tannic acid or dyes and (3) greasy dressings. A wet dressing is suitable for a fresh burn which has not been cleansed or an old one which has become septic. An occlusive dressing is successful if the wound is clean and the burned area one that is relatively immobile. It is therefore not good as a first-aid dressing, nor for the fingers face, and flexures. Greasy dressings are very comfortable and proper on the face and fingers but should not be used too continuously as the raw surface gets grease-lodged and indolent. They are very satisfactory as the skin heals.

In every case of severe burn there is a series of symptoms and signs which must be looked for and if found treated. The details of treatment vary but particular points should be checked over in each patient.

1 Any case assessed as a severe burn, at first requires intravenous plasma. It is extremely valuable to have an estimation of the hemoglobin before treatment is started, and essential to have this determination made as soon as possible from beginning to end the chart of the hemoglobin percentage is as important as that of the temperature and pulse. Glucose-saline solution should be given intravenously until it is apparent that the patient can drink enough, without vomiting to prevent dehydration. A fluid-intake-and-output chart gives the surgeon complete information on this point.

2 As to local treatment, despite the early appearance of organisms in a burned area there is no desperate rush to get at the wound. Under morphine alone the burned areas are cleansed with aseptic precautions blisters snipped and the wounds very carefully dressed with tulle gras or vaselined gauze. The ends of the fingers are guarded by a Cramer wire splint which projects beyond the tips. Morphine is given for pain.

3 It is advisable to leave the dressings untouched for 4 days at least. In the interval the patient needs fluids, glucose and rest. If his burns are reasonably comfortable he will sleep better with a hypnotic than with morphine.

4 After from 3 to 7 days according to the general condition, it is time for the first dressing. For an extensively burned patient there is nothing

seen. Instead, the epidermis was being desquamated and the cells and debris were being removed by phagocytes.

The author explored an inguinal canal in a human being into which a whole skin graft had been sutured for a large direct hernia three months before. The graft was firmly attached to Poupart's ligament, the medial aponeurotic aspect of the internal oblique and the insertion of the rectus sheath in the pubis. The edges of the graft could not be ascertained with certainty and the appearance closely resembled a normal inguinal canal. The dense fibrous tissue and deformity of anatomy seen in the recurrent fascial repairs were absent. The graft microscopically showed highly vascular connective tissue without dermal or epidermal elements. No hair remnants were found. Microscopically no evidence of cyst formation was seen—only a number of giant cells.

The author believes that no contraindication to the use of these grafts in human beings has been found to date and he used them in a series of 119 inguinal hernias of all types: 6 umbilical hernias, 10 ventral, 1 femoral hernia and 1 epigastric. In this group there were 3 cases of mild sepsis, 1 case of scrotal hematomas, and 12 cases of mild postoperative bronchitis. Late postoperative complications have not been seen, and as yet it is too soon to study recurrency figures. The author prepares the skin (for three days) by careful shaving and washing with ether soap and warm water for 10 minutes. Spirit compresses and a sterile bandage are then applied. He suggests a gas-oxygen-ether or spinal anesthesia to give maximum muscle relaxation so the graft can be placed under maximum tension. The skin for the graft is encompassed on the original incision and measures about 1 by 1". It is prepared by removing the subcutaneous fat. The ends are cut off, and the graft is split for a distance of $\frac{1}{4}$ inch down one end. The graft is placed in the inguinal canal, and the apex of the V is brought around the cord. Three 30-day chromic sutures are used to hold the medial margin of the graft to the lower aspect of the rectus sheath the fascia over the symphysis and the medial edge of Poupart's ligament. The graft is then sutured to the shelving edge of Poupart's ligament and the aponeurotic medial edge of the internal oblique with sutures $\frac{1}{4}$ inch apart. Care is taken that the graft be sutured under great tension. The outer pedicles of the graft are then joined laterally to the internal ring and outside of the emerging cord.

The patients are allowed up on the twentieth day since fascia does not heal firmly in less than three weeks. The same principles can be adopted for direct hernias and whole skin grafts can be used for final re-enforcements for umbilical, ventral, and epigastric hernias. ROBERT R. BRADLOW, M.D.

Green, R. W. Levenson, S. M. and Lund, C. G.: Nylon Backing for Dermotome Grafts. *V. Eng-land J. M.* 1945 233: 268.

In the use of the drum technique of skin grafting, as described by Padgett in his book on skin grafting

(Springfield Charles C. Thomas 1943) some surgeons have been using a backing on the drum such as plico film (Webster) and cellophane (Evans). The author suggests a fine-gauge nylon cloth for the same purpose. Before the graft is cut the drum is coated with dermatome cement and the backing is cemented to the drum as smoothly as possible. New coats of cement are then applied to the backing and to the donor site and the graft is cut as described by Padgett. The graft with its back is removed from the drum and placed on the recipient site. No sutures are needed to maintain the graft at its original size and tension, it being merely maintained in place by even elastic pressure provided by a suitable pressure dressing with or without external splinting.

The advantages claimed by the author for his nylon-cloth backing are (1) that nylon can be sterilized as easily as any textile and is physically unchanged after sterilization and (2) that grafts backed with nylon conform better to irregular surfaces than do those backed with cellophane, yet in spite of the relative limppiness of the nylon before it is attached to the skin it prevents contraction of the graft as well as cellophane or sutures.

A case history is given and 6 figures to illustrate the method and the results of treatment.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Harkins, H. N., Cope, O., Evans, E. I., Phillips, R. A., and Richards, D. W. Jr.: *Therapy of Burns. J. Am. M. Ass.* 1945 13 475.

This memorandum is released by authorization of the National Research Council and Office of Scientific Research and Development. Chemotherapy with penicillin and sulfonamides is not within the scope of the present discussion.

Following burns, there is loss of extracellular fluid salts, and plasma. In patients with minor burns involving less than 10 per cent of the body surface, it is generally agreed that restitution takes place by the ingestion of fluids and food, according to the desires of the patient. However, in patients with severe second-degree or third-degree burns of at least one of the following areas (face and neck, dorsal or ventral surface of chest, dorsal or ventral surface of abdomen, upper extremity and dorsal or ventral surface of lower extremity) parenteral fluid administration is necessary.

Three dangerous phases are observed in severe and inadequately treated burns:

1. Shock may be present for as long as 48 hours after the burn, but clinical signs may not be obvious since generalized vasoconstriction may keep the blood pressure at satisfactory levels even though cardiac output is greatly diminished. Therefore, vigorous fluid therapy is essential during the first 3 days of every case of severe burn.

2. The period of toxemia (from 48 to 128 hours, occasionally up to the third week) is manifested by

In some of the more advanced cases a typical change in skin coloring i.e. a bluish brown tinge not only of the skin around the wound but also of the face the lips and the body in general was noticed. Pulse rates were frequently above 120 and temperatures ranged from 100 to 102 F. In spite of sulfonamide therapy, anemia was found to be out of proportion to the estimated blood loss. Wound odor best described as rotten or decaying meat or "mousy" was noticed in only one third of the cases and crepitus was found only occasionally. Gas gangrene occurred in the following regions in order of frequency buttocks thighs shoulders upper and lower extremities.

Treatment consisted of measures against shock and anemia followed by early radical and extensive debridement. Foreign bodies pieces of clothing and dirt, were carefully removed in order to prevent recurrence, and all damaged muscle tissue was excised. Sulfonamide compounds proved of little value against clostridia but were very effective against other contaminants. Penicillin in large doses applied locally intramuscularly and intravenously was found to be an excellent adjunct, but only if used in conjunction with surgery and antitoxin. Gas gangrene antitoxin was given after surgery in doses corresponding to the degree of toxemia. In the absence of sensitivity a minimum of 18 therapeutic doses were given, each containing 10,000 units of antitoxin against clostridium welchii and clostridium septicum, and 1,500 units of the antitoxin against clostridium oedematiens. Preoperative administration of antitoxin appeared to be of little value.

Eleven (11.5%) of the 96 patients died as the direct result of gas-gangrene infection.

ARTHUR J. LEASER, M.D.

Walker Taylor P. N.: The Treatment of Tropical Ulcer. *Lancet Lond.*, 1945 149 40.

Tropical ulcer is an acute process usually seen in West Africa. The ulcer located on the lower leg or foot, is a dirty sharply marginated lesion, the base of which is covered by a dark purulent slough and the ulcer is surrounded by a zone of edema. The patient with this disease is not obviously ill and suffers little pain.

Good results were obtained by the following simple measures:

1. Elevation of the limb to reduce the edema and improve the circulation
2. The application of moist warm dressings
3. The topical use of penicillin or a sulfonamide dusting powder

4. Early skin grafting if the ulcer is large. The same disease may affect the toes and is then called ulcerative onychia. On a toe the ulcer develops under the nail or under the cuticle. It is often necessary to cut away the dead nail and the dead cuticle in order to establish drainage. The drainage trench is then packed open at each dressing. Other than the treatment of ulcerative onychia is the same

as in cases in which the ulcer is found on the leg or foot.

Three complications are mentioned: fibrosis of the ulcer bed in long-standing cases; infestation with the guinea worm; and osteomyelitis.

The average period of incapacity of the patient after admission was 37.2 days.

DAVID H. LYNN, M.D.

Archer G. T. L.: Bactericidal Effect of Mixtures of Ethyl Alcohol and Water. *Brit. M.J.*, 1945 2 148.

The author has re-studied an old but still important problem and has utilized satisfactory technical methods in well controlled experiments. His findings are valuable and apparently his conclusions represent a significant addition to the practical information available.

To test the bactericidal effect of various dilutions of ethyl alcohol, 30 experiments employing 6 different methods were carried out. From the practical point of view, this work was done to determine the optimal dilution for use on the skin. When alcoholic solutions were applied to the normal or moist skin the findings differed from those obtained with the application of solutions of equal strength to dry surfaces.

It was found that on a dry surface the effective range of strengths of alcohol for the killing of non-sporing bacteria is between 90 per cent and 50 per cent. Solutions of 95 per cent and above were found to be partially ineffective and solutions of 100 per cent, markedly so. On the skin the results were different because the normal skin is more or less moist. On the skin, 100 per cent alcohol was commonly found to be effective especially on moist skins and under tropical conditions of temperature and humidity whereas under similar conditions concentrations of 60 per cent to 65 per cent showed a certain loss of efficiency. Therefore the author recommends that as a rule and under all climatic conditions 80 per cent alcohol is probably the strength most suitable for sterilization of the skin.

Ether was found to be quite ineffective as a sterilizing agent for the skin, since its effect is very slight on staphylococci and streptococci although it is effective against certain bacillary forms.

DAVID H. LYNN, M.D.

Lovell D. L.: Penicillin: Its Tropical Use as a Bacteriostatic Agent for the Palliative Treatment of Chronic Stasis Ulcers of the Lower Extremities. *Arch. Surg.* 1945 51 22.

The secondary infection in chronic stasis ulcers responds readily to topical applications of penicillin. This drug is thought to be superior to other bacteriostatic agents that are generally used for this purpose. In the early stages of the condition rapid healing occurs when the infection and stasis are controlled. Healing is delayed in the cases of chronic ulceration because of extensive fibrosis of the edges and the poor arterial blood supply.

BENJAMIN GOLDMAN, M.D.

which makes him so comfortable or the dressing so easy as a bath. In the early stages during the separation of sloughs, a daily bath seems best. Later when the wound reaches the healing stage, it may make the granulations soggy.

5 Food with extra proteins is the next care. Equally important is attention to the bowels.

6 The hemoglobin should be checked at any time that the patient's condition causes anxiety or if progress is slow and always on the tenth day. If it is below 80 per cent it should be checked daily and if it continues to fall a blood transfusion should be given.

7 As the patient's general condition improves first-aid grafting where skin has been destroyed becomes urgent.

JOSEPH K. NARAT M.D.

McCartan, W., and Fecitt, E.: First Aid for Phosphorus Burns. *B U I J* 945, 316.

The facility with which copper combines with active phosphorus to form copper phosphide has been the basis of most methods of first-aid treatment of persons contaminated with phosphorus. The standard treatment suggests that the burning phosphorus should be extinguished with water and by keeping the burned area damp. The burn is treated with aqueous solutions of sodium bicarbonate and copper sulfate. The principal objections to this treatment are that such solutions are cumbersome to carry and are not likely to be immediately available in civil defense and under active service conditions although speedy application is, of course, all-important. Also the number of persons contaminated may be so large that immediate active surgical attention to all is not possible and in the meantime it is necessary to repeat the application of the solution—not the best treatment for an already shocked patient. There is further the danger that repeated applications of fluid may wash particles of phosphorus to the periphery with the risk of peripheral burns.

The danger of phosphorus-containing incendiaries during air attacks led the authors to investigate this matter with a view to producing a substance which fulfilled the following requirements: (1) it should be readily available in a compact form; (2) all of the remedies should be contained in the one compound; (3) it should immediately extinguish the phosphorus and inactivate the products of phosphorus combustion, i.e. phosphorus pentoxide and phosphoric acids; (4) it should be viscous and stick to the skin so as to remain in position, and also hold the particles of phosphorus in situ; and (5) it should be easily removed by warm water.

The authors employed *sapo mollis* as the base for incorporating copper sulfate, and developed a compound with a final content of 4 per cent of copper salts. The damage to tissue by burning phosphorus is thought to be due not only to the heat of combustion and to the corrosive action of the phosphoric acids formed as the terminal result of such combustion, but also to the intensely hygroscopic action

of phosphorus pentoxide, which is formed in the intermediate stage of the change. Phosphorus pentoxide "mops up" water with great avidity and with the production of intense heat. According to the authors when a film of water sufficient to extinguish the phosphorus flame is applied to the skin, it will not be adequate to provide the pentoxide with enough water to supply its needs; thus tissue fluid is called on and this produces further damage. For this reason a high proportion of water is mixed with the compound. It was also believed that water loosely held in depth over the area by such a compound might act as a better conductor of heat than air and that in this way the heat generated by the change— $P_2O_5 + 3H_2O \rightarrow 2H_3PO_4$ —would be more easily removed from the site of the injury.

A 25 per cent solution of copper sulfate in water is prepared and the requisite amount of this to give a final content of 4 per cent copper salt is heated in a boiling flask. *Sapo mollis* is heated in a water bath, and the copper sulfate solution is added hot by constant trituration on a slab. Copper precipitates as oleate, and this is thoroughly incorporated into the base between each addition. It is advisable to add the copper sulfate solution in small successive portions. The resulting compound is a homogeneous mass and samples have kept very well for at least twelve months. The pH of the final compound, determined electrically is 8.65 at 19°C. and 8.25 at body temperature.

The authors conclude from results of animal experimentation and observations on clinical material that copper sulfate ointment in addition to being an excellent first-aid measure for phosphorus burns is of value in the healing stages also since it has reduced the healing time of burns in striking fashion. The authors suggest that it be combined, in subsequent treatment, with sodium bicarbonate solution because the latter allows easy removal of the ointment if the burn is to be inspected, assists in the disposal of any phosphorus which may still persist after ointment treatment and tends to reduce the healing time of the burn.

Langley, F. H., and Winkelstein, L. B.: Gas Gangrene. A Study of 96 Cases in an Evacuation Hospital. *J Am Med Ass* 945 28 783.

Ninety-six cases of clinical gas gangrene infection were observed at an evacuation center in northern France during the period between July and December 1944. The average incidence of gas-gangrene infections per 1,000 battle casualties was 16. The incidence was highest in prisoners of war (63 per 1,000 battle casualties) and was considerably lower in American and Free French troops (9.9 per 1,000 and 12.3 per 1,000 respectively). The higher incidence in the prisoners of war is explained by the longer intervals between the time of the initial injury the first-aid dressing and the surgical repair.

Early general signs of gas gangrene were (1) pain (2) tightness of the dressing and (3) signs of toxic

The average dose of sodium pentothal was 23 c.c. and the average dose of curare was 80 units. The duration of postoperative narcosis was minimal. All but 40 patients left the operating room either awake enough to open their eyes and respond or with an adrenergic reflex.

MARY KARP M.D.

Knight R. T. and Baird J. W.: Prolonged Anesthesia. *Surgery* 1945 18 33

A report is made of 1,000 consecutive operations which required anesthesia of three hours or more duration, and were collected in a period of about three years. This series has been tabulated with regard to the average age of the patients, preoperative conditions, preoperative medications and anesthetic agents used.

Morphine and scopolamine became the anesthetics used preoperatively in most cases although morphine was not given in the brain cases.

Spinal anesthesia has gained in popularity in the past year a long-acting single dose of the anesthetic being preferred to the continuous technique.

Cyclopropane without any addition of ether was used in the more recent group of operations but a sufficient concentration of the drug was employed to produce apnea and then artificial or controlled respiration was induced by manual manipulation of the breathing bag. Excellent muscle relaxation was produced, and the operative and postoperative course and the recovery time of these patients were found to be better than with any preceding type of anesthesia.

The combination of single-dose spinal anesthesia with cyclopropane and controlled respiration gave an excellent picture with an even better postoperative course, less prostration, and more rapid recovery of vigor than was found in patients who had been anesthetized by cyclopropane alone.

Curare was added to the armamentarium in May of 1943 and it became increasingly popular as time went by. Its special advantages were the lessened incidence of catheterization and headache as compared with spinal anesthesia.

Of 130 cases of brain surgery 103 received cyclopropane and in most of the cases an intratracheal tube was inserted. All major chest surgery was accomplished under cyclopropane given intratracheally. The inflatable cuff which was used around the intratracheal tube was described and the advantages are mentioned.

A discussion of cautery and fulguration in relation to the agent used was given with the conclusion that the type of anesthesia used and the benefit of the cautery or fulguration were both too advantageous to be given up in view of the closed system of anesthesia and careful draping. With hundreds of trials the authors have been unable to pick up an explosive sample of gas farther than 3 inches from the wide-open end of the gas tubing.

Postoperative pulmonary complications occurred following 84 of the 1,000 long surgical procedures.

MARY KARP M.D.

Baptist A. Jr. Five Years Experience with Caudal Anesthesia in Private Obstetric Practice. *Am J Obst.* 1945 50 180.

In five years 318 obstetric cases were delivered under caudal anesthesia by the author and seen for the routine six weeks of postpartum check up examination. Forty five of the total represent obstetric complications such as breech presentations or transverse arrests in which procedures other than outlet forceps deliveries were done. Many of these were seen in consultation. In every case but one the anesthesia was excellent and no supplementary anesthetic was required. In one case in which the outlet was directly posterior and delivery was prolonged (arrested second stage) unilateral anesthesia only was obtained and inhalation anesthesia was necessary. One cesarean section was done in this group of 45 cases but supplementary anesthesia was unnecessary. Caudal anesthesia for cesarean section is hazardous because the solution must be driven higher than usual to get satisfactory anesthesia and this carries an increased risk of vascular collapse.

The remaining 273 cases represent normal obstetric patients who were delivered under caudal anesthesia by means of elective outlet forceps. All had had perineotomy.

This total group of 318 cases in 316 of which caudal anesthesia was entirely satisfactory, represents an attempt to administer caudal anesthesia in 320 cases. In 2 cases the caudal canal could not be entered although it seemed clearly palpable.

In the total group of 318 cases there was no maternal mortality and no complication from the anesthetic, either maternal or fetal. One stillborn fetus was delivered by breech extraction after a prolonged second stage of labor the baby having died in utero before the patient was seen in consultation. One other baby died 4 days postpartum from erythroblastosis. All of the other babies were born in excellent condition. Caudal anesthesia offers a tremendous advantage in delivery of the premature infant. The technique is described.

EDWARD L. CORNWELL, M.D.

Kremer M.: Meningitis after Spinal Analgesia. *Brit M J* 1945 2 309

The possibility of introducing infection into the subarachnoid space by spinal tap has been recognized from the time that lumbar puncture was first performed, and this possibility must be considerably increased if anything is injected into the theca. If infection is introduced along a needle track it may obviously lodge anywhere in the course of that track. With lumbar puncture the possible localities are the skin, subcutaneous tissues, vertebrae, epidural space, and subarachnoid space.

The author reports 7 cases of meningitis following spinal anesthesia and 1 case following diagnostic lumbar puncture. The condition is a low-grade meningitis caused by a variety of organisms introduced at the time of lumbar puncture. The main clinical features are the chronic nature of the illness

Finland M., Miesda, M., and Ory E. M.: Oral Penicillin. *J Am M Ass* 945, 1945, 315.

A dose of 90,000 units of penicillin given by mouth one-half hour before breakfast, regularly gave serum levels comparable with those obtained from 15,000 or 30,000 units given intramuscularly. The levels obtained in the serum when the same amount of penicillin was given one-half hour after breakfast were quite varied and unpredictable.

As compared with normal persons achlorhydric individuals had more sustained serum levels from oral penicillin taken before a meal, and after the postprandial dose they had higher as well as better sustained levels than normal persons.

The serum levels obtained with ordinary penicillin in saline solution were at least as high and as well sustained as those obtained with any of the special oral preparations tested. This was true when the drug was given both before and after meals except, possibly when aluminum hydroxide gel was used in addition to the saline solution of penicillin after a meal.

Effective penicillin levels could be fairly well maintained with several oral preparations given in 90,000 or 100,000 unit doses every 2 hours.

The results of preliminary clinical trials in gonorrhea and in pneumococcal pneumonia suggest that oral penicillin therapy is feasible in these conditions. They also suggest that oral therapy should prove effective in other infections in which low doses of parenteral penicillin have proved adequate. Penicillin should be given parenterally to initiate therapy in all infections which are severe, and in those which require prolonged treatment with parenteral doses as shown by experience. SAMUEL KAHN, M.D.

Ross, S., and McLendon P. A.: Penicillin by Mouth. *J Am M Ass* 1945, 190, 37.

Adequate therapeutic blood concentrations of penicillin, after oral administration, can be obtained when the drug is protected against inactivation by gastric acidity. A method of providing this protection, by the use of a double gelatin capsule hardened by formaldehyde-alcohol immersion, together with preliminary neutralization of the hydrochloric acid in the stomach, was adopted.

Administration of a 100,000 unit capsule every 3 hours, by this method, provides constant therapeutic penicillin levels well within or above the effective antibacterial range of most susceptible organisms throughout the course of treatment.

A clinical trial of this method on 10 children with gonorrhea 2 with pneumonia, and 2 with cellulitis resulted in prompt recovery.

The relatively large doses of penicillin employed produced no toxic manifestations.

SAMUEL KAHN, M.D.

Turton, E. C.: Penicillin by Intramuscular Infusion. *Brit. M J* 945, 83.

The author summarizes his experience after treating 30 patients with continuous and intermittent

intramuscular injections of penicillin. The instrument used for the continuous intramuscular drip was the Endrip 2 (McAdams *Lancet*, 1944, 2, 336). The intermittent injections were administered by the nursing staff after it had been instructed by medical officers.

All patients were located in a 30-bed ward and had been especially selected as having severe compound fractures.

Of the 30 patients 24 were quite emphatic that they preferred the continuous intramuscular drip to the intermittent injections. By 4 in whom both pectoral and thigh regions were injected the thigh was strongly preferred but the patients disliked frequent changes of the site of injection. At first the needles were changed every third or fourth day but later the tendency was to leave them in longer at the most for seven days.

Fifteen patients admitted to some tenderness over the needle site but pain was not a feature of the drip in any instance. Subsequent stiffness of a limb with delayed return to full function was not found in any case nor was there any abscess formation or pus in the needle tract.

The general impression at the end of the series was that continuous intramuscular infusion is the method of choice for the patient and no more laborious than the intermittent injection.

LEONARD J. PROUDMAN, M.D.

ANESTHESIA

Brady J.: The Use of Curare in Sodium Pentothal Nitrous Oxide Oxygen Anesthesia. *Asthma* 945, 6, 38.

The author reports the use of curare in sodium pentothal nitrous oxide oxygen anesthesia for 30 consecutive surgical operations in which relaxation was excellent. The initial dose of sodium pentothal is injected intravenously in an amount sufficient to produce narcosis to a level at which there is no response to questions. Two liters of oxygen and 2 liters of nitrous oxide are then administered by the semi-closed carbon dioxide technique. When the skin is incised, an initial dose of from 60 to 80 units of curare is given intravenously from a small syringe, separate from that used for the sodium pentothal. Additions of 20 units may be necessary when the peritoneum is opened. In operations lasting longer than from 30 to 45 minutes supplementary doses of from 20 to 40 units are administered to maintain relaxation and sodium pentothal is injected intermittently to maintain anesthesia.

The curare depression can be effectively overcome by the intravenous use of from 1 to 2 c.c. of a 1:1000 solution of prostigmine, plus complementary support of inadequate respiration.

Relaxation of muscles and peritoneum has been comparable to that seen in spinal anesthesia. The preanesthetic medication was morphine sulfate and atropine sulfate given hypodermically 1½ hours before the scheduled time of operation.

The average dose of sodium pentothal was 23 c.c. and the average dose of curare was 80 units. The duration of postoperative narcosis was minimal. All but 40 patients left the operating room either awake enough to open their eyes and respond or with an active lid reflex.

MARY KARP M D

Knight R. T. and Baird J. W. Prolonged Anesthesia Surgery 1945 18 33

A report is made of 1,000 consecutive operations which required anesthesia of three hours or more duration and were collected in a period of about three years. EDWARD L. CORRYALL, M D

Kremer M: Meningitis after Spinal Analgesia Brit M J 1945, 2 309

The possibility of introducing infection into the subarachnoid space by spinal tap has been recognized from the time that lumbar puncture was first performed, and this possibility must be considered if increased if anything is injected into the theca. If infection is introduced along a needle track it may obviously lodge anywhere in the course of that track. With lumbar puncture the possible localities are the skin, subcutaneous tissues, vertebral epidural space and subarachnoid space.

The author reports 7 cases of meningitis following spinal anesthesia and 1 case following diagnostic lumbar puncture. The condition is a low grade meningitis caused by a variety of organisms introduced at the time of lumbar puncture. The main clinical features are the chronic nature of the illness.

and the tendency toward relapse. It is suggested that this is due to the formation of adhesions containing infected cerebrospinal fluid which is liberated from time to time. These adhesions may cause spinal block or hydrocephalus.

Three theories have been advanced to account for the production of this form of meningitis.

The chemical theory suggests that the condition is entirely due to the irritating action of the spinal anesthetic and that infection plays no part. There is good evidence of the irritating effects of the spinal anesthetics but it would appear that with ordinary clinical dosage this irritation comes on at once is short lived, and quieted down without relapse as the irritant is disposed of.

The next possibility is that the meningitis is secondary to infection elsewhere in the body. As a secondary meningitis is not possible in the clean cases one may argue that it is an unlikely explanation in the others.

The third possibility is that the meningitis is due to the introduction of infected material along the lumbar puncture needle. It is true that in a number of cases it has not been possible to isolate the organism as might be expected in an infectious condition. The author stresses the point that failure to cultivate an organism is compatible with an infectious origin. This is not infrequently seen in the meningitis which follows open wounds of the brain—an infectious condition by all other standards. The delay which usually occurs between the operation and the onset of meningitis is very suggestive of a phase of multiplication of an organism as a preliminary factor to the phase of clinical activity. Probably the most convincing evidence in favor of the infectious theory is the cessation of fresh cases with the enforcement of aseptic technique. There can be little doubt that the spinal anesthetics are mild irritants and it is possible that the reaction to this irritation with the outpouring of protein-rich fluid gives reasonable conditions for an organism to gain a foothold.

The only satisfactory treatment is prophylaxis. It should be possible to avoid these unhappy cases completely. If because of an emergency a rigid technique is not possible, then spinal anesthesia should not be used. Unfortunately the causal organism is often not susceptible to present-day chemotherapy i.e. sulfonamides and penicillin but this should not prevent an early adequate trial of these substances. The formation of adhesions causing spinal block is common and calls for no special treatment but if hydrocephalus occurs surgical relief may be necessary.

JOSEPH K. NARAY, M.D.

Stevens, E. J.: Pentothal Sodium: Its Use in Continuous Intravenous Anesthesia and a Method of Preserving It in Solution. *Anesthesiology* 1945 6 376

Various methods have been advocated for the administration of pentothal sodium. The author

reports his experience with the use of 0.4 to 0.1 per cent (1:250 to 1:1000) dilutions of the agent in 100 cases. The 0.4 per cent dilution is made by adding 4 gm. of pentothal sodium to a regular commercial liter bottle of 5 per cent glucose in normal saline solution. A glass drip meter is inserted into the bottle and a screw clamp is used on the tubing to regulate the flow. A No. 18 gauge needle is usually recommended to permit rapid injection of the solution.

The diluted pentothal sodium can be kept in solution for several days thus eliminating unwanted waste.

When anesthesia is induced with a 0.4 per cent solution, the fluid is allowed to flow in a steady stream or to drip rapidly. The patient is allowed to count out loud and ordinarily will be asleep in from 45 to 75 seconds. As soon as the desired depth of anesthesia is reached the rate of flow is reduced. Clotting in the needle is prevented by this method and easy controllability is an added advantage.

The 0.3 and the 0.1 per cent dilutions of the pentothal sodium are used in conjunction with local and spinal anesthetics and have special value for an apprehensive patient who wishes to be asleep. The use of these dilutions is entirely sedative and the anesthesia is dependent upon the local or spinal anesthetic agents. It has been found that these dilutions give greater relief of nausea and vomiting than 100 per cent oxygen when spinal anesthesia is used.

MARY KARP, M.D.

McCann, J. C.: Anesthesia by Combined Intravenous Pentothal Sodium and Local Nerve Block. *J. Exp. Med.* 1945 233 55

The combination of intravenous administration of pentothal sodium and regional nerve block has become the anesthesia of choice for major as well as minor surgical operations, with few exceptions at St. Vincent's Hospital, Worcester, Massachusetts. The exceptions are (1) operations in children under seven or eight years of age, because of the small caliber of the veins (2) operations about the neck in the absence of intratracheal intubation, because of the too easy stimulation of reflex laryngospasm (3) operations on patients over sixty years of age who are to undergo a prolonged operative procedure because of the unsatisfactory metabolic destruction of large doses of the drug and the danger of pulmonary edema from prolonged depression and (4) operations on patients with vomiting, asthma or abdominal distention.

During the past year the author employed pentothal sodium intravenously as the major anesthetic in 64 per cent of approximately 800 surgical cases of all types.

Frequently pentothal sodium (intravenous) as the sole anesthetic does not provide adequate muscular relaxation without the danger of respiratory depression, and surgeons have employed various combinations. Small amounts of ether and cyclopropane quickly and completely make up for these deficiencies.

of the pentothal sodium. Although some surgeons report that nitrous oxide and oxygen afford additional help, the author believes that the results are not comparable to those procured by the complementary use of regional nerve block. Only 3 to 4 per cent of his cases required ether or cyclopropane as supplemental anesthesia.

In this series pentothal sodium was administered as a 1 per cent solution by the continuous-drip method, which has been well described in the literature. In the infrequent cases in which the veins were so small as to cause an unsatisfactory rate of flow a 2 per cent solution was used. After induction, the drug was administered during the period of maintenance in repeated and grouped subminimally in amounts of either 5 c.c. or 10 c.c. according to the rate of metabolic destruction of the drug in the given case. Between each subminimal fraction there was a wait of one minute to observe the effect on the respiratory center. The drug was given with the usual intravenous-infusion apparatus and the drops were regulated through a Murphy drip to about 250 per minute for induction and between 150 and 240 per minute for maintenance. A companion infusion apparatus provided for continuous administration of saline or glucose solution during the intervals between the pentothal-sodium fractions and for the instantaneous administration of plasma or blood without disturbance of the patient during the operation. The intervals between fractions were from five to fifteen minutes. Having observed the syringe technique for several years, the author adopted this method as the simplest, most dependable and most flexible way of administering pentothal sodium.

Local anesthesia by means of 1 per cent novocain was used to take up the deficiencies of the pentothal sodium. Patterns of blocking the sympathetic or intercostal nerves according to the type of operation were mapped out from the background of general experience with regional anesthesia.

This complementary use of the two agents provided a completely satisfactory anesthesia comparable in all respects and superior in many to spinal or deep general anesthesia. It was accomplished with the administration of only moderate doses of pentothal sodium. If the two methods are effectively combined the result provides a speedy safe type of anesthesia, with an induction and recovery experience strikingly free of unpleasant and uncomfortable episodes such as are associated with the other principal anesthetic methods. Nausea and vomiting are infrequent postoperative catheterization of male patients is rarely necessary and in cases of hemorrhaphy has practically disappeared postoperative headache does not occur the administration of parenteral fluid except as required by the technical exigencies of the operation is reduced almost to the vanishing point and early ambulation is favored.

The author believes the combination of intravenous administration of pentothal sodium and anterior splanchnic block constitutes an ideal anesthetic for all operations on the stomach, spleen, gall bladder and ducts. The combination has been particularly popular on the European continent, and no anesthetic fatalities had been reported up to 1937. In the author's cases the use of anterior splanchnic block resulted in a reduction of about 1 gm. in the average total dosage of pentothal sodium required.

The purpose of anterior splanchnic block is to deposit an anesthetic dose of novocain retroperitoneally at the level of the first and second lumbar vertebrae between the aorta and the inferior vena cava. This is an isthmus point or meeting place for all sympathetic nerves and plexuses deriving from the greater and lesser splanchnic nerves and the sympathetic trunks which supply the stomach, duodenum, pancreas and transverse colon.

The author presents a modified technique that he devised for carrying the splanchnic needle to assured and safe contact with the first lumbar vertebra.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Peake, J. D.: Radiation Therapy in Uterine Fibroids. *Semin. M. J.* 1945 38 480

The author reports on 390 cases of uterine fibroids treated by radiation therapy and followed up from six months to ten years. All the patients had symptoms usually abnormal uterine bleeding and especially menorrhagia. Their average age was forty-two years and the ages ranged from twenty-six to seventy-seven years. The diagnosis was based on the history and pelvic examination by at least two physicians; some patients received preliminary diagnostic curettage. Patients with complicated pelvic conditions, those in whom the diagnosis was doubtful and those with very large tumors were not treated by this method but were referred for surgery. On the other hand for patients with some concurrent illness contraindicating surgery, such as coronary heart disease, radiation was considered the treatment of choice for fibroids with bleeding.

Roentgen therapy alone was given to 186 of the patients, with from 350 to 300 roentgens measured in air given daily through one of the two or three pelvic portals 15 cm. in diameter until from 6 to 12 treatments had been given within two weeks. The factors were 200 kv.p., 30 ma., 50 cm. distance, a filter of 6 mm. of aluminum plus 0.5 mm. of copper of high value layer o.p. The larger doses proved the more successful.

Eighty-six cases had only radium, inserted after dilatation and curettage from 35 to 50 mgm. with 1 mm. of platinum filter being left in the uterine cavity until a total dose of from 800 to 3,000 mgm. hrs. was reached. In addition, 18 cases which had not responded well to a course of roentgen therapy were given radium in smaller doses.

In all but 3 cases bleeding stopped in from six weeks to three months. No menopausal symptoms occurred before the third month, but thereafter two-thirds of the patients developed hot flashes, increased nervousness or headache. Treatment consisted of barbiturates, estrogens, and reassurance. In 2 cases bleeding recurred after the use of stilbestrol, and in 1 case after theelin, but it stopped when the drug was discontinued. No patient gave a history of loss of libido following irradiation and no pregnancies occurred, but several of the younger patients eventually re-established a normal menstrual cycle.

The author concludes that uterine fibroids respond well to irradiation therapy as indicated by the arrest of bleeding and reduction in size of the tumor that complications are slight, and that irradiation is the method of choice for patients with concurrent disease rendering surgery dangerous.

LILLIAN DONALDSON M.D.

MISCELLANEOUS

Hooper H.A., and Dean, C.A.: Studies in Hodgkin's Syndrome. The Therapeutic Use of Radioactive Phosphorus. *J. Lab. Clin. M.* 1945, 30 678.

The authors report the treatment of 11 patients with histologically proved Hodgkin's disease by bi-weekly intravenous, and occasionally oral administrations of radioactive phosphorus (P^{32}). The single doses ranged from 1 to 3 or m.c. of intravenous equivalent. Therapy was discontinued as soon as an increase in the activity of the disease or bone involvement, became evident and this occurred in 10 of the patients. (One patient died during treatment and another patient failed to return for further treatment.) The maximum and minimum periods during which treatment occurred, before additional evidence of disease activity developed were thirty-seven weeks and ten weeks, respectively.

The conclusion was reached that radioactive phosphorus was not of therapeutic value and that successful subsequent x-ray treatments in 8 of the patients indicated the superiority of the latter method. The treatments affected the blood in a similar manner as did treatments with roentgen rays, e.g., all cases showed a drop in the leucocyte count. Of interest was the intense depression of the platelet count in 7 of the cases, which persisted even after the administration of P^{32} had been discontinued. No clinical evidence of hemorrhage occurred.

The authors discuss briefly the preparation of the radioactive phosphorus isotope (P^{32}) by bombardment of regular phosphorus with a ten million volt deuteron beam in the Ohio State University cyclotron.

OSCAR D. SCHWARTZ, M.D.

Clarkson, J.R., Bong, J.W., Holmes, B., and Ellis, F.: Symposium: Physical, Biochemical, and Therapeutic Aspects of Volume Dose. *Brit. J. Radiol.* 1945 18 233, 35 38, 240.

In 1935, it occurred to Ellis that a certain advantage may be derived from a knowledge of the total quantity of energy of radiation absorbed by the body during the course of treatment. This he called the "volume dose." In 1940 Mayneord carried out a series of experimental investigations to determine the magnitude of this dose. As a basic unit he suggested the gram-roentgen, which is the energy conversion when 1 roentgen is delivered to 1 gm. of air and is approximately equal to 85 ergs. A megagram-roentgen (one million gram-roentgens) is approximately equivalent to a calorie.

In the present symposium Clarkson discusses the physical aspects of the volume dose. He pays attention to the value of the dose (1) during whole-body irradiation, and (2) during limited field irradiation.

1. A wax model patient of elliptical cross-section, and divided into slabs has been constructed (in con-

junction with Mayneord) By placing condenser ionization chambers in some of these slabs and by making use of a focal skin distance of 250 cm. so that the entire body is irradiated at one time measurements have been made for various situations. The volume dose was then calculated from the doses recorded by the ionization chambers. It was found that for equal surface doses the volume dose varied greatly with the quality of the radiation. This is important in devising protection regulations against stray radiation. It appears that a person working in a "deep therapy" department may absorb five times as much energy for an equal measured stray radiation dose as one engaged in diagnostic work.

2. No systematic measurements were carried out with the limited fields of irradiation. One condition studied, however led to two interesting results (a) it was found that a large proportion of the energy absorption (about 30 per cent in the particular case) occurred in parts of the body receiving less than 10 per cent of the dose at the center of the field on the surface and (b) it was also found that if a limiting diaphragm of 3 mm thickness of lead was used (with roentgen rays of 3.7 mm copper half value layer) the total energy absorption was almost 50 per cent greater than when one of 11 mm. thickness was used which means that the common limiting diaphragms are not thick enough.

Mayneord recently supplied graphs and tables which make it possible to calculate the volume dose for various methods used in roentgen and radium therapy. In radium therapy the volume dose is expressed in gram-roentgens per milligram hour.

Boag discusses the energy absorbed by a patient during x ray treatment. He gives physical data which are complementary to those of Clarkson, in that they refer entirely to limited fields. They have been obtained from measurements carried out (in conjunction with Walter) on the celluloid model patient devised by Grimmer (1939-1942) for this purpose. This model is constructed of graphited cellulose acetate plates, 6 mm. thick, spaced apart by 2 mm thick washers of the same material. The graphite makes the plates electrically conductive. Alternate plates are connected together and the two groups of plates thus formed are connected to opposite poles of a battery. A sensitive galvanometer included in the circuit measures the total ionization current collected from all the air gaps where there are in a radiation field. Certain requirements must be fulfilled if the measurements made with such a model are to give a true picture of the energy absorption in the human body. These are briefly described.

The following situations have been studied: field on pelvis, field on chest, short focal skin distance, head fields, dependence on half value layer, mass of fields, effect of size of the patient and the distribution of absorption in different parts of the body. The investigations were carried out with roentgen rays of 2 to 4 mm. copper, half value layer and the curves so obtained plotted. The conclusion was that the volume dose depends upon the area and site of the

field and to a much smaller extent upon focal skin distance, linear dimensions of the patient and half value layer of radiation.

Holmes discusses the biochemical aspects of volume dose. The author states that none of her observations were made with consideration of the volume dose but that in few cases enough data are available to allow of calculation.

It is not possible to draw positive conclusions although there remain some clear suggestions for future work.

It is inevitable that investigations of general biochemical effects should be related to x ray sickness. A great deal of work has been done on this. Among the various phases studied are: acidosis, alkalosis, changes in the calcium, sodium and potassium concentrations of blood tissues and urine, changes in the blood cholesterol, liberation of histamine, the role of cortical hormone and, more recently, the responsibility of purines. It is interesting in connection with the purines that uric acid, the end product of purine metabolism, is found in increasing amounts in animal tumor cells twenty-four hours after irradiation.

Ellis discusses the clinical aspect of the volume dose in radiotherapy. He calls attention to the fact that the term mega gram roentgen because it assumes unit density of the patient might be better replaced by a volume unit. However no such neat term is available since the analogous "volume" term would have to be mega cubic centimeter.

Unlike Mayneord's wax patient and Grimmer's celluloid patient, human beings are complex physico-chemical systems subject to mental and a multitude of other influences. Because of this biological phenomena are difficult to correlate with volume dosage.

The relationship of volume dose and tumor dose can be changed by varying (1) the field size (2) the focus-skin distance (3) the quality of the beam and (4) the arrangement of the number of fields.

1. The effect of field size. The volume dose is calculated by the formula

$$D \times A \times \frac{\text{max. r./min. possible}}{\text{r./min. for field size considered}}$$

where D is read from a graph (of Hapsey) and A = area. It results from this formula that other things being equal the volume dose is almost proportional to the field area. For example if the field is 400 cm² and the beam passes through 20 cm. of tissue, the volume dose is 13 x 400 x $\frac{1}{20}$ x dose and for a field of 50 cm² it is 13 x 50 x $\frac{1}{20}$ x dose. The ratio of the volume doses therefore is $\frac{400}{50} \times \frac{1}{21}$ for the same surface dose. For the same depth dose the ratio becomes more nearly equal to that of the areas. A circular field of 10 cm. in diameter will give a less volume dose than a square field of 10 cm. side.

2. The effect of the focus-skin distance. Other things being equal the greater the focus-skin distance the smaller the volume dose and thus the less the untoward general reaction.

3. The effect of the quality of the beam. This has been demonstrated by Phillips when he treated car-

carcinoma of the rectum with 6,000 roentgens by using in one case 200 kv. and in the other 1,000 kv. The volume dose was much greater with the high voltage beam for the same surface dose other things being equal.

4. The arrangement and number of fields. Ungar in 1933 analyzed the factors in this respect. He gives examples of arrangements of fields for carcinoma of the cervix in relation to "economy quotient and volume dose. The economy quotient is defined as the ratio of the minimum tumor dose divided by the difference between the maximum and minimum tumor doses. It was found that other things being equal the arrangement which gave the greater economy quotient gave the smaller volume dose.

In correlating the biological phenomena with the volume dose, special attention must be paid to the general or constitutional as distinct from local phenomena. They may be divided into subjective and objective. The former include malaise, nausea, vomiting, headache, etc., which it is impossible to measure or dissociate from the effects of local phenomena. The latter are divisible into two classes (1) blood counts and (2) other measurements.

1. Bush, in 1933, published a curve correlating the volume dose with the proportional decrease in lymphocytic count relative to the initial count. The author himself found so much variability and his experience with other features of the blood count were even less encouraging.

2. Other measurable quantities are the corpuscular volume, color index, sedimentation test and blood pressure. None of these varies as readily as does the number of lymphocytes with the volume dose.

As a whole the conclusion is drawn that the chief value of the volume dose at present is in evaluating

principles of treatment and protection on physical grounds rather than being a practical guide to biological effects.

T. LARCOMA, M.D.

Camp, J. D., and Moreton, R. D.: Radiation Necrosis of the Calvarium (Report of 5 Cases). *Radiology* 1945 45 13.

The authors found 5 cases of radiation necrosis of the calvarium in a series of 2,036 cases of intracranial tumors which were treated by roentgen rays and with or without surgical measures at the Mayo Clinic. However, since no systematic follow-up roentgenograms were available in all cases it is probable that the incidence was higher.

The 5 cases are presented in detail and illustrated with their respective roentgenograms. In the first case the radiation necrosis was discovered five years after the roentgen therapy. In the second case 1 year later, in the third case 12 years later, in the fourth case 14 years later and in the fifth case 17 years later.

In none of these patients was there any symptoms referable to the necrosis of the bone. Because of this and since the calvarium does not function as a structure of stress the authors believe that no attempt should be made to reduce the roentgen dose which is necessary to destroy the intracranial tumor for which the treatment is originally undertaken. The long survival obtained in the cited cases well justifies the soundness of the technique of irradiation employed.

The knowledge of the possibility of necrosis of the calvarium following intensive roentgen irradiation of the skull is important for the reason that it may obviate confusion in the diagnosis with other similar conditions.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Carter S. J.: Serum Amylase Findings in Chronic Alcoholic Patients with Acute Severe Abdominal Symptoms. *Ann Surg* 1945 122 117

The purpose of this article is to emphasize the significance of the high serum amylase values found in a group of 11 patients suffering from acute abdominal symptoms in whom there was a history of chronic alcoholism. The symptoms and signs upon admission of these patients were vomiting severe epigastric pain and marked upper abdominal rigidity with or without epigastric tenderness. In this type of patient, the diagnosis of acute alcoholic gastritis is usually made while occasionally an unnecessary exploratory laparotomy is done for a possible surgical lesion. The preceding alcoholic debauch evidently precipitates changes in a digestive system that has been impaired by the prolonged excessive use of alcohol.

Four of the 11 patients in this series were subjected to operation and in each instance edema about the pancreas was noted. The peritoneal fluid was of a thin sanguineous character. In the remaining 7 patients the high amylase levels were the chief factor in deciding against operative intervention. These 7 patients were discharged well.

The cause of the elevated serum amylase is considered to be the rapid destruction of the acinar membranes of the pancreas and the sudden escape of the enzyme into the blood stream. Evidence concerning relationships between the ingestion of large amounts of alcohol, chronic alcoholic gastritis and pathological changes in the pancreas is discussed.

JOHN L. LINDBQVIST, M.D.

Herbut, P. A., and Scarsdale, T. M.: Diffuse Hepatic Necrosis Caused by Sulfadiazine. *Arch Pathol, Chic.* 1945 40 94

A review of the literature discloses reports on 4 cases of acute diffuse hepatic necrosis resulting from the use of sulfanilamide. To these the authors added 2 cases of this condition following the administration of sulfadiazine. One patient had not previously received sulfonamide compounds whereas the other had been given a course of treatment with sulfadiazine one month before a second course was administered.

It is thought that while focal hepatic necrosis may result from outright chemical action of the sulfonamide compounds on the liver cells, diffuse hepatic necrosis may be the result of inherent or acquired hypersensitivity of the liver for the drug.

Of the two types of renal damage ascribed to the sulfonamide compounds the authors believe that the one type wherein crystals or concretions are found in and beyond the renal tubules is due to the direct

action of the sulfonamide compounds on the kidney. The more severe type, however, showing tubular necrosis casts and interstitial congestion and edema with foci of inflammatory cells is due, they believe to the accompanying disease process which may be infection, intestinal obstruction, jaundice, or some other condition, and not to direct action of the drug on the renal parenchyma. EARL O. LATIMER, M.D.

Rosenberg, A., Jr., and Welch, H.: A Study of the Types of Hypersensitivity Induced by Penicillin. *Am J Hyg* 1945 51 138

The authors state that a study was made to determine the incidence of hypersensitivity of the tuberculin type to crystalline penicillin sodium in individuals who had had no previous contact with this drug. Studies were made also of the sensitivity induced by the injection of commercial or crystalline penicillin sodium. The procedure which was followed is given in detail.

To determine the incidence of the tuberculin type of sensitivity to penicillin 644 persons were tested. Each person was injected intradermally on the volar surface of the forearm with 0.1 c.c. of penicillin sodium containing 1,000 units. When a positive reaction resulted a retest was made with crystalline penicillin. Eight individuals exhibited hypersensitivity of the tuberculin type when tested initially. Attempts to show a passive transfer of the hypersensitivity with use of the Prausnitz-Kustner technique and the Urbach-Koenigstein method both failed.

The authors state that it has been previously noted that following intradermal injections of commercial penicillin in man there developed a flaring phenomenon in certain persons which appeared only after a variable number of injections had been made. This phenomenon consisted of an increase in redness and itching at the sites of former injections following the intradermal injection of crystalline penicillin sodium in the new site. Persons who exhibited this type of reaction failed to do so after a rest period during which no injections were made. The authors injected 9 individuals intradermally with 1,000 units of commercial penicillin sodium, 1,000 units in 0.5 c.c. of saline solution at each of 10 different sites. These injections were repeated in approximately the same areas five and ten days later, a total of thirty injections being given. Following the first series of 10 injections some of the subjects showed evidence of chemical irritation, all who showed the irritation developed it from the same lots of penicillin. Following the second series of 10 injections reactions occurred in 3 people. One individual who had previously received injections showed the flaring phenomenon described, at the site of the old injections. Another developed urticaria thirty hours after injection. Two days after the reaction had subsided

cinoma of the rectum with 6 000 roentgens by using in one case 200 kv and in the other 1,000 kv. The volume dose was much greater with the high voltage beam for the same surface dose other things being equal.

4. The arrangement and number of fields. Ungar in 1943 analyzed the factors in this respect. He gives examples of arrangements of fields for carcinoma of the cervix in relation to economy quotient and volume dose. The economy quotient is defined as the ratio of the minimum tumor dose divided by the difference between the maximum and minimum tumor doses. It was found that other things being equal the arrangement which gave the greater economy quotient gave the smaller volume dose.

In correlating the biological phenomena with the volume dose special attention must be paid to the general or constitutional as distinct from local phenomena. They may be divided into subjective and objective. The former include malaise nausea vomiting, headache etc. which it is impossible to measure or dissociate from the effects of local phenomena. The latter are divisible into two classes: (1) blood counts and (2) other measurements.

1. Bush, in 1943, published a curve correlating the volume dose with the proportional decrease in lymphocytic count relative to the initial count. The author himself found no such reliability and his experience with other features of the blood count were even less encouraging.

2. Other measurable quantities are the corpuscular volume, color index, sedimentation test, and blood pressure. None of these varies as readily as does the number of lymphocytes with the volume dose.

As a whole the conclusion is drawn that the chief value of the volume dose at present is in evaluating

principles of treatment and protection on physical grounds rather than being a practical guide to biological effects.

Rostenberg, A. Jr. and Welch, H.: A Study of the Types of Hypersensitivity Induced by Penicillin. *Am J M Sc.* 1945 210 158.

The authors state that a study was made to determine the incidence of hypersensitivity of the tuberculin type to crystalline penicillin sodium in individuals who had had no previous contact with this drug. Studies were made also of the sensitivity induced by the injection of commercial or crystalline penicillin sodium. The procedure which was followed is given in detail.

To determine the incidence of the tuberculin type of sensitivity to penicillin, 644 persons were tested. Each person was injected intradermally on the volar surface of the forearm with 0.1 c.c. of penicillin sodium containing 1,000 units. When a positive reaction resulted, a retest was made with crystalline penicillin. Eight individuals exhibited hypersensitivity of the tuberculin type when tested initially. Attempts to show a passive transfer of the hypersensitivity with use of the Prausnitz-Kustner technique and the Urbach-Koenigstein method both failed.

The authors state that it has been previously noted that following intradermal injections of commercial penicillin in man there developed a flaring phenomenon in certain persons which appeared only after a variable number of injections had been made. This phenomenon consisted of an increase in redness and itching at the sites of former injections following the intradermal injection of crystalline penicillin sodium in the new site. Persons who exhibited this type of reaction failed to do so after a rest period during which no injections were made. The authors injected 9 individuals intradermally with 10,000 units of commercial penicillin sodium 1,000 units in 0.5 c.c. of saline solution at each of 10 different sites. These injections were repeated in approximately the same areas five and ten days later a total of thirty injections being given. Following the first series of 10 injections some of the subjects showed evidence of chemical irritation all who showed the irritation developed it from the same lots of penicillin. Following the second series of 10 injections reactions occurred in 2 people. One individual who had previously received injections showed the flaring phenomenon described at the site of the old injections another developed urticaria thirty hours after injection. Two days after the reaction had subsided

an attempt was made to transfer the sensitivity of the latter to 3 normal individuals by the Prausnitz-Kustner technique. Passive transfer was not successful. In the third series of 10 injections the reaction varied considerably. Four subjects showed erythema around all injected sites within from fifteen to thirty minutes. Wheals, varying in size from 5 to 15 mm., developed in 2 of these individuals and subsided within a period of from one to two hours. The other 4 test subjects showed, in addition to whealing and marked erythema at the sites of injection, the flaring reaction at the old sites of injection. One of the group of 4 exhibited the most intense reactions.

The authors attempted to induce sensitivity by varying the technique of administration. Only 1 person developed an increase in sensitivity and this individual was one of those who had been injected intradermally with crystalline penicillin sodium. Because of the reactions shown, a series of patch tests was made to determine whether the eczematous type of hypersensitivity could be demonstrated. The tests were made with commercial penicillin sodium. Although all patch tests were negative intradermal tests made at the same time with crystalline penicillin sodium again revealed a positive tuberculin type of sensitivity to crystalline penicillin sodium and also gave a positive reaction at the site of a previous intradermal injection of either commercial or crystalline material.

After the skin of 5 other people was sand-papered sufficiently to cause a faint pin-point punctum of blood, patch tests were made. These were negative, and indicated that the negative patch tests resulted from the lack of a hypersensitive shock tissue rather than from inability of penicillin to penetrate the horny layer.

An attempt was made therefore to transfer passively the hypersensitivity exhibited by individuals in whom the hypersensitive state had been induced by intradermal injection. Passive transfer antibodies could not be demonstrated. Precipitin tests made on the serum of the 4 test subjects were also negative.

To determine whether the sensitivity to penicillin would also extend to the spores of penicillin notatum, a heat killed suspension was made containing 50,000 spores per cubic centimeter. Intradermal injections of 0.1 c.c. were given to 5 persons who exhibited a tuberculin type of hypersensitivity to penicillin. There were no immediate or delayed reactions.

In conclusion, the authors state that 5 per cent of 144 individuals tested with crystalline penicillin sodium exhibited a positive reaction of the tuberculin type despite the fact that none of these individuals had any prior contact with penicillin. Repeated multiple intradermal injections of penicillin sodium caused the development in some people, of reactions of the Arthus type, and some of these also developed a tuberculin type of hypersensitivity.

Since the material at test strength is not a primary irritant a positive reaction indicates that these in-

dividuals are specifically hypersensitive to this material. It is assumed that these individuals have had previous contact with penicillin sodium or with an immunologically equivalent material. Contact with penicillin sodium as such can be arbitrarily eliminated. However contact with penicillin appears to be quite likely since it is a fairly common genus of fungi. It may be ingested or inhaled and, in susceptible individuals produces a subclinical infection with a consequent alteration in their immunological responses.

HAROLD F. THURGOOD, M.D.

Hines, L. E., and Kessler, D. L.: The Effect of Penicillin on Heparin Tolerance. *J Am M Ass* 945: 1870-4.

Studies of the effect of penicillin on heparin tolerance were carried out following the occurrence of extensive visceral hemorrhages in 2 patients with bacterial endocarditis who were treated by penicillin.

The first case was that of a female 37 years of age. Serial blood cultures showed hemolytic streptococci. During the period between May 27 and June 8, 1944 this patient had received 700,000 units of penicillin intramuscularly. Two days following the first injection her temperature was found to be normal and spectacular symptomatic improvement was shown. However in 25 days following her admission to the hospital she suddenly developed generalized tonic and clonic convulsions which lasted for a period of 2 hours she became comatose and died 3 days later. At autopsy the anatomic findings were extensive spontaneous subarachnoid hemorrhage of the base of the brain secondary to a large hemorrhage of the pons, almost healed endocarditis to the mitral valve (hemolytic streptococci, clinical) small recent infarct of the left lung, ancient infarct of the spleen and cystitis of the urinary bladder.

The second case was that of a female 23 years of age who had been pregnant for a period of 5 months. Serial blood cultures were negative after 21 days and the patient delivered a viable baby in the seventh month of pregnancy. During the next 12 days 1,000,000 units of penicillin were given intramuscularly and in addition, 100 mgm. of heparin were given during the first 5 days. The patient's temperature gradually subsided to normal after a period of 7 days. Death occurred 13 days following delivery. At autopsy the anatomic findings were as follows: vegetative and ulcerative endocarditis of the aortic and tricuspid valves with erosion and perforation of both valves, acute perforated ulcer of the stomach with extensive hemorrhage into both the lesser and greater peritoneal cavities, extensive petechial hemorrhages of the peritoneum, pericardium, pleurae and serosa of the small intestine and other minor findings. The greater peritoneal cavity contained air and more than 1 liter of partially clotted blood.

The 2 patients presented the following points of similarity: proved bacterial endocarditis early improvement by penicillin therapy and fatal termination from hemorrhage 1 by extensive cerebral hemorrhage the other by widespread, intraperitoneal

mesenteric and pleural hemorrhages. One patient received heparin while the other did not.

Studies were made on the effect of penicillin on the clotting mechanism, and particularly the effect of penicillin on the reaction of the blood to heparin.

Other studies were made on a series of patients before penicillin was administered, during the course of therapy and after the penicillin had been discontinued. These studies included erythrocyte counts, hemoglobin determinations, prothrombin time, platelet counts and heparin tolerance curves. In each case the penicillin was administered intramuscularly in doses of 10,000 Oxford units every 3 hours. One-half of the patients studied had diseases which were considered unsuitable for penicillin therapy and therefore served as controls.

Although in the 10 cases studied there were no significant changes in the erythrocyte count, hemoglobin, platelet count or prothrombin time, a definite change was produced in some patients in the heparin tolerance curve. In 2 patients very profound effects were registered in their sensitivity to heparin. There was no effect on the tolerance curve in 3 patients; there was a slight but inconclusive increase in 5 patients.

These studies suggest that it is advisable to run heparin tolerance sensitivity tests as a precautionary measure if heparin and penicillin are to be used at the same time. RICHARD J. BENNETT, JR., M.D.

Marriott H. L. Medical Problems of the South East Asia Command. *Lancet* Lond. 1945 248 679

The biggest single lesson learned from the experience of the last three years has been the tremendous importance of disease in wasting manpower. No figures of value are available for 1942. In 1943 the admission rate to hospitals and other medical units was just under 1,200 per 1,000 per annum. In 1944 it was just under 1,000 per 1,000 (this is equivalent to every man in the force being admitted to the hospital in the course of a year). Disease has played an enormously greater part in man-power wastage than has enemy action. The ratio of casualties from sickness to casualties from wounds in 1943 was 122:1 and in 1944 a year of heavy fighting it was 19:1.

At least four fifths of the sickness casualties have been due to diseases which may be classified as preventable. This being the case it would seem rational to employ a very much higher percentage of personnel in the business of prevention. Any men given to the hygiene units by the hospitals and other curative units do not represent a loss to the last two units because the diminished incidence of disease will result in much less work for them. One medical officer engaged in hygiene can save the work of 10 medical officers in hospitals.

After disease prevention the most important function of the medical services is the rapid cure and return to duty of all sick and wounded. In this respect the value of diagnosis and treatment at the earliest possible moment cannot be overstated. The

diseases particularly malaria, diarrhea, the dysenteries and skin diseases have in common that their response to treatment is proportional to the speed with which it is applied. What is done at once matters much more than what may be done several days later.

A compressed review such as this does not lend itself to summarizing. The author hopes that its brevity relative to the extent of its subject may excuse a tendency to dogmatism and perhaps to oversimplification. JOHN E. KIRKPATRICK, M.D.

Welch C. S., and Tuhy J. E.: Combined Injuries of the Thorax and Abdomen. *Ann Surg* 1945 122 358.

Welch and Tuhy discuss their experiences in the definitive treatment of 83 patients with combined injuries of the thorax and abdomen treated in an evacuation hospital. There were 4 principal types.

Thoracoabdominal wounds—those in which a missile enters the pleural cavity first traverses the diaphragm and lodges in or traverses the peritoneal cavity. These made up the largest group (53 cases).

Abdominothoracic wounds—those with primary involvement of the abdomen followed by perforation of the diaphragm and injury to the thoracic cavity. The 13 cases in this group were placed in a separate category because of the somewhat different problems and prognoses which they presented.

Thoracodropenitoneal wounds—those involving the diaphragm and retroperitoneal structures (commonly the kidney) without apparent involvement of the peritoneal cavity. The 6 cases under this heading are grouped together as the order in which these structures were injured seemed to make little difference in the outcome.

Thoracic and abdominal injuries—these include (1) separate missile wounds of both cavities 7 cases, (2) a subcutaneous injury to the chest and abdomen by blunt trauma 2 cases and (3) missile wounds of one body cavity associated with blunt injury to organs of the other 2 cases with penetrating chest wounds associated with contusion of the kidney in 1 instance and of the spleen in the other belong in the last category.

The wounds were on the right side in 48 cases with 8 deaths and on the left side in 33 cases with 12 deaths. Both patients in whom the chest was involved on one side and the abdomen on the other died. The operability rate was 88 per cent. Half of the patients had associated injuries.

Five principal types of operation were carried out: (1) thoracotomy and transdiaphragmatic operation, (2) thoracotomy and transdiaphragmatic operation combined with celiotomy, (3) celiotomy alone, (4) repair of the kidney and (5) wound exploration with suture of the pleura if necessary.

Five of the 40 patients with injury on the right side and 7 of the 30 with injury on the left side all of which were operated upon died during the period of observation. The operative mortality rate was 17 per cent. STEPHEN A. ZIEGLER, M.D.

Snyder H. E.: The Management of Intrathoracic and Thoracoabdominal Wounds in the Combat Zone. *Ann Surg* 1945 33 333

Snyder thinks that few casualties with wounds of the chest who survive to be evacuated from the battle field would die if properly equipped trained surgeons were available for their care and first priority management, consisting of prompt care and surgery in the most forward hospital installations were provided.

A surgeon familiar with both thoracic and abdominal surgery is best qualified to treat severe wounds of the chest which are encountered in the most forward hospitals and an anesthetist well trained in endotracheal anesthesia for thoracic surgery is essential. Oxygen-ether administered endotracheally through a closed apparatus capable of positive pressure is the preferred anesthetic in all perforating and penetrating wounds of the chest whereas prompt well-directed resuscitative measures, plus thoracotomy are required for the recovery of patients with thoracoabdominal wounds with continuing intrathoracic hemorrhage and large bronchial fistulas.

The preferred management of open chest wounds consists in the proper occlusion with gauze and adhesive strapping until the patient is in a hospital equipped and staffed to do intrathoracic surgery.

Early and repeated aspiration of hemothoraces, without air replacement, is recommended, and hemorrhage has not recurred because of this practice. Moreover it is believed that early aspiration of large pneumothoraces and continuous aspiration by catheter water-seal drainage of pressure pneumothoraces must be accomplished to secure a high survival rate in such conditions.

Intercostal nerve block, to relieve pain, to promote deeper breathing, and to facilitate expulsion through the coughing up of blood and mucus in the tracheobronchial tree, is an important adjunct to therapy whereas tracheal catheter suction has an important place in the pre- and postoperative management of chest wounds.

At the termination of every operation upon a patient with a chest wound, a bronchoscopic aspiration of blood and mucus from the trachea, main stem bronchi and lobar bronchi should be done. It may be indicated in the preoperative, operative and postoperative periods when less radical measures fail to clear the tracheobronchial tree.

Replacement therapy particularly with whole blood, is most important, and autotransfusion of pleural blood should be used whenever practicable. Care must be exercised to give the blood slowly after the systolic blood pressure has reached 80 mm Hg. and to give no more blood than is necessary to attain adequate resuscitation.

Most wounds of the chest need only débridement of the chest wall, preceded and followed by proper chest management replacement therapy and oxygen therapy. There are certain indications for thoracotomy through the wound, and fewer indications for formal thoracotomy by separate incision.

Surgery of chest wounds with few exceptions should be done first in the case of multiple wounds, thoracoabdominal wounds and combined intrathoracic and abdominal wounds. Most thoracoabdominal wounds are best handled first by the thoracic approach a celiotomy being performed only if abdominal wounds cannot be cared for by the transdiaphragmatic route.

Evacuation from the pleura of blood, air and all foreign bodies and irrigation of the pleura with physiological salt solution is desirable in the surgery of perforating and penetrating wounds of the chest. On the other hand, complete expansion of the lung by its inflation to the chest wall and evacuation of all pleural fluid and air should be effected at the end of all operations in which the pleura is opened.

Sulfonamide or penicillin therapy should be continued until the pleura is free of all air and fluid.

STEPHEN A. ZIEGLER, M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Saphir W.: Filariasis. *J Am Med Ass* 1945 33 114

The value of the old dictum that a diagnosis of infectious disease should not be made in the absence of the demonstration of the causative organism, is undisputed yet, if this dictum were adhered to the early diagnosis of filariasis could not be made in most cases. A delayed diagnosis until such a time as microfilariae become demonstrable might prevent the only effective procedure, namely early removal of the patient from the endemic area. Furthermore it would create a large reservoir of carriers on whom the mosquitoes could feed, and thus cause widespread propagation of the disease.

It is for this reason that a syndrome such as has been outlined must be depended upon, in order to reach at least a tentative diagnosis.

There seems little doubt that the clinical picture as described in the original article was due to filarial infection. It is true that the findings were not as typical as were those described in the textbooks nor were there typical filarial attacks accompanied by constitutional symptoms such as fever, general malaise and prostration. On the other hand, there was a history of exposure to day and night biting mosquitoes in an area where the native population was known to be heavily infected with filariasis. There was a more or less generalized lymphadenopathy and various types of genital lesions were present. Periodic aggravations of palms and swellings so characteristic of the later stages of the disease were commonly observed. However the asymptomatic stage also peculiar to late cases was not noted in this series. Nocturnal pains and particularly nocturnal orchidodynia, were frequent complaints.

Laboratory tests as performed were of little diagnostic help, with the possible exception of the test for eosinophilia which was present in 40 per cent of the cases. The diagnosis must be based on clinical evidence.

DOUGLAS R. MONTGOMERY, M.D.

Weich H. Price, C. W. and Chandler V. L.: Oral Penicillin. *J Am Med Ass* 1945 138 845

The successful oral administration of penicillin may depend upon complete neutralization of the acidity of the stomach plus a relatively slow release of the drug from some chemical which adsorbs it readily. Thirty cubic centimeters of aluminum hydroxide gel (U.S.P.) were added to 100,000 units of penicillin dissolved in water. 30 c.c. of magnesium magna (U.S.P.) were added with constant agitation to 100,000 units of penicillin dissolved in water. The penicillin and metallic hydroxides were centrifuged at high speed, and it was found that approximately 50 per cent of the penicillin which had been added to the aluminum hydroxide remained adsorbed on the sediment. In the case of magnesium hydroxide approximately 25 per cent of the penicillin remained adsorbed on the sediment. The metallic hydroxide sediments were washed several times with distilled water. Approximately 50 per cent of the original amount adsorbed still remained. It appears that penicillin adsorbs more readily by aluminum hydroxide than by magnesium hydroxide but that magnesium hydroxide is more retentive.

Oral administration of penicillin treated with aluminum hydroxide was carried out. These tests were carried out with the use of 100,000 units of penicillin sodium in 20 c.c. of water and 30 c.c. of aluminum hydroxide (U.S.P.). Bloods were taken at stated intervals following ingestion. Control tests were carried out with the use of 100,000 units of untreated penicillin sodium. With the aluminum hydroxide, about 50 per cent of the blood samples at twenty-four hours showed a concentration of penicillin equivalent to from 0.03 to 0.045 unit per cubic centimeter of serum. In the control test with the untreated penicillin sodium, no penicillin could be demonstrated in the blood samples collected at the seventh and the twenty-fourth hour.

Other tests were carried out whereby instead of giving one initial large dose the same amount of penicillin was given in four full and equal doses of 25,000 units each at two-hour intervals. With this method the concentration of penicillin in the blood did not drop below approximately 0.08 units per cubic centimeter until after the eighth hour. From the eighth until the twelfth hours a concentration of 0.06 units or more per cubic centimeter was maintained. Between the twelfth and the fifteenth hours the concentration dropped to 0.036 unit per cubic centimeter and this level was maintained through the twenty-eighth hour.

By contrast 6 persons given 100,000 units of untreated penicillin sodium in 25,000 unit doses every two hours had an assayable level for from seven to eleven hours. With the use of magnesium hydroxide in similar tests the results were similar to those obtained with penicillin modified with aluminum hydroxide. The amount of magnesium hydroxide used caused some laxative effect in 60 per cent of the persons using it. Magnesium hydroxide nevertheless was as effective as aluminum hydroxide in the

maintenance of penicillin in the blood after administration. 72 per cent of penicillin was excreted in the urine over a period of twenty-four hours. After these metallic hydroxides and penicillin have been prepared and kept at refrigerator temperature both mixtures have been found to be stable for a period of at least thirty days. The strong neutralizing effect of aluminum hydroxide on the acid of the stomach is established.

There are indications which suggest that perhaps there is some absorption of penicillin directly from the stomach into the blood stream, and there is also some indication of an accumulative effect. When this penicillin aluminum hydroxide was given in fractional doses, the serial concentrations of penicillin did not fall below an effective therapeutic level until after the twenty-fourth hour and this is especially significant when it is considered that the penicillin aluminum hydroxide was not given until after the sixth hour. RICHARD J. BROWETT JR., M.D.

DUCTLESS GLANDS

Anderson T. and Trier M. Alternating Hyperthyroidism and Myxedema. *Acta med scand* 1944, 119 345

A case of alternating hyperthyroidism and myxedema in a woman who was 42 years of age on her first admission to the hospital in August 1935 is described. At this time she showed pronounced symptoms of exophthalmic goiter although her metabolism was normal. She was given iodine treatment and her metabolism fell to pathologically low values accompanied by the development of well marked symptoms of hypothyroidism. From that time up until March, 1941 she had 3 alternating periods of hypothyroidism and hyperthyroidism, decreased thyroid function developing when she was given iodine and increased function on thyroid medication. As the alternating changes in her condition became unbearable to the patient subtotal thyroidectomy was performed on March 12, 1941 after she had been given preoperative iodine treatment. After the operation she had hypothyroidism for the fourth time and was treated with thyroid gland tablets. After a transitory overdosage which resulted in symptoms of hyperthyroidism the thyroid treatment was discontinued in June 1943 and the patient has had no treatment since. In April 1944 her metabolism was still normal.

Apparently the normal condition of this patient was one of hypothyroidism in the course of which she developed a pathological condition of hyperthyroidism or dysthyroidism.

Zondek reported a similar case in 1943 in connection with which he held that conditions of hypofunction and hyperfunction of the thyroid gland must be caused by neurogenic or humoral factors outside of the gland and that the transition from exophthalmic goiter to myxedema is not due to temporary functional exhaustion of the thyroid.

AUDREY G. MORGAN M.D.

Muether R. O., Sexton, D. L., Macdonald, W. and Von Brueggen, J. T.: Clinical Experiences with Thiouracil. *Sark. M. J.*, 1945 38 443.

The authors present a review of the history of the development of thiouracil therapy and report an analysis of 35 cases. Each patient was thoroughly studied and all pertinent clinical laboratory studies were made. They find that thiouracil brings about a complete remission of symptoms in thyrotoxicosis. Available information indicates that it will accomplish all that surgery accomplishes in bringing about symptomatic relief. In Graves disease not previously treated with iodine, the effect is as quick and dramatic as the best results from iodine therapy, and in nodular toxic goiter improvement occurs in from four to eight weeks. In either condition the effect is lasting.

In recurrent hyperthyroidism thiouracil has brought about the relief of symptoms whereas iodine has failed.

Persistent symptoms following thyroidectomy with a normal basal metabolic rate may be relieved by suppression of the basal rate slightly below normal with thiouracil.

Thiouracil acts by inhibiting the formation of thyroxine, probably by direct action on the thyroid gland. In patients previously treated with iodine improvement is delayed.

As a preoperative measure, thiouracil is effective over a prolonged period, which makes it superior to iodine. Toxic effects of the drug may be serious. They can be minimized by cautious administration of the drug for the first few days and by limiting the dosage to 0.4 or to 0.6 gm. per day.

Thiouracil gives promise of leading to a medical cure of thyrotoxicosis and equals and, in many instances is an improvement over any previous form of therapy. Time may prove that it is of greatest value when used in conjunction with surgery. At this writing it cannot be said how long it will be necessary to continue the drug nor what unforeseen systemic effects may arise from its prolonged usage. Secondary systemic disturbances found in hyperthyroidism may be expected to show improvement as hyperthyroidism improves.

In several patients with nervous instability not associated with hyperthyroidism, suppression of the basal metabolic rate with thiouracil has had no effect on symptomatology. BENJAMIN GOLDMAN, M.D.

Hissell, G. W.: The Magnesium Partition in Hyperthyroidism with Special Reference to the Effect of Thiouracil. *Am. J. M. Sc.*, 1945 210 95.

Diffusible and nondiffusible serum magnesium fractions were determined in 24 hyperthyroid and 18 normal persons. In the thyrotoxic cases the nondiffusible fraction ranged between 3 per cent and 58 per cent of the total serum magnesium, with an average of 30.5 ± 1.9 per cent. In the normal persons the nondiffusible fraction varied from 17 to 43 per cent of the total, with an average of 30.4 ± 1.1 per cent. The author's data indicate the average total diffusible

and nondiffusible serum magnesium levels of hyperthyroid patients to be slightly lower than the comparative average values for normal individuals. However, the average value for the percentage of nondiffusible magnesium is almost identical in the two groups. The range of the percentage of bound magnesium in hyperthyroidism is strikingly varied, being just twice as great as the range for normal individuals.

Thiouracil apparently has no constant effect on the magnesium fractions in hyperthyroidism.

It is suggested that the variability in the magnesium fractions in thyrotoxicosis is the reflection of alterations in the metabolic processes.

BENJAMIN GOLDMAN, M.D.

Louis, P.: Nine Cases of Graves Disease Developed in Connection with Thyroid Gland Therapy. *Acta. med. scand.* 1945 83.

Histories are given of 9 cases in which exophthalmic goiter developed during or shortly after thyroid medication. In 7 of the cases the treatment had been given for simple obesity. The treatment had been continued for periods of from one month to several years. All of the 9 patients presented indications for subtotal thyroidectomy which was performed in 7 cases after preoperative iodine treatment. The results of operation were good. Two of the patients refused operation. Not only were the clinical features those of Graves disease, but histological examination showed the typical histological picture of this disease.

The conclusion to be drawn from these cases is that thyroid gland preparations should never be given for obesity. AUDREY G. MORROW, M.D.

Brown, E.: Exophthalmic Goiter Developing after Treatment with Thyroid Preparations. *Acta med. scand.* 1945 22 3.

In the Medical Out Patient Department of the Rugehospital in Copenhagen from January 1940 to September 1944, 15 patients were treated for thyrotoxicosis that developed after taking thyroid preparations. This constituted 3.2 per cent of the total of the patients with thyrotoxicosis treated during this time. In addition, the author had 3 similar cases in his private practice, a total of 18 cases. A table is given in the original article showing the clinical data in these cases. All of the patients were women, most of them in the climacteric age group. In 11 of the 18 cases the thyroid medication had been given for simple obesity. It was given for myxedema in only 3 cases.

The question arises as to why so few patients who take thyroid therapy develop thyrotoxicosis and the answer lies in the fact that a predisposition to thyrotoxicosis seems to exist in certain individuals. Such a predisposition has been demonstrated in 45 per cent of the patients in whom thyroid disease follows the administration of thyroid therapy.

Four of these patients showed a pronounced unilateral exophthalmos. This symptom was also re-

ported in 3 of the 28 cases of exophthalmic goiter following thyroid therapy that have been described in the literature previously. Therefore, if patients with thyrotoxicosis show marked unilateral exophthalmos they should be questioned carefully as to whether they have had thyroid medication.

It is estimated that in Denmark the amount of thyroid preparations consumed is 3 times as great as that required for the existing cases of myxedema. The greater part of this excess of thyroid is used by patients with obesity. Thyroid treatment should never be given for simple obesity and the public should be warned of its dangers.

AUGUST G. MORGAN, M.D.

Ljunggren E.: Surgical Treatment of Goiter Especially of Toxic Goiter (Hyperthyroidism) in Sweden. *Acta chir scand* 1944 89 346

Graphs are presented showing the increase in the number of thyroidectomies in the hospitals of Sweden from 1930 to 1942. This increase applies to both toxic and nontoxic cases. The number of operations for hyperthyroidism nearly tripled in this period being 536 in 1930 and 1,460 in 1942. The operative mortality decreased during this period from 4 to 2.3 per cent. During this same period the number of "medical deaths" from hyperthyroidism that is deaths without operation decreased about 50 per cent. The number of operations for nontoxic goiter more than doubled during this period 616 being performed in 1930 and 1,391 in 1942. During the whole period the mortality from this operation was less than 2 per cent and during the last 2 years it was only 0.2 per cent.

Results have been improved since the introduction of preoperative iodine treatment in 1935 and also by improved postoperative treatment with iodine, glucose, and vitamin B. Patients with hyperthyroidism are particularly sensitive to infection and if pulmonary infections can be prevented the patient's life can often be saved. Early operation is advisable in hyperthyroidism before the heart and other organs, particularly the liver have been damaged beyond repair.

AUGUST G. MORGAN, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Christensen A.: On Carotid Body Tumors. *Acta chir scand*, 1943 88 453

The anatomy, histology, and physiology of the carotid body are discussed and photomicrographs given of some typical tumors. The subjective symptoms of carotid tumor are slight as a rule. The most characteristic objective symptoms are the location of the tumor and its relation to the carotid arteries. Extirpation is the only radical treatment. Irradiation alone should not be given unless operation is contraindicated or impracticable as these tumors are generally radioresistant.

Some surgeons advise against operation in these tumors on account of the great risk, while others advise operation in spite of the risk. About 10 per

cent of them become malignant. The most serious complications are lesions of the carotid arteries or jugular vein followed by fatal hemorrhage or air embolism. Hemorrhage can be controlled by placing a tape around the common carotid artery at the beginning of the operation. When the internal jugular vein can be isolated from the tumor a ligature should be placed centrally and peripherally from the tumor and the fixed piece of vein resected. The danger of air embolism can be prevented in this way.

The author describes 7 cases of his own 5 in females and 2 in males the ages of the patients varying from 24 to 60 years. In 6 of the cases the growth was on the right side and in 1 it was on the left. The diagnosis was established before operation in all of the cases. In 2 cases primary extirpation was performed in 1 biopsy and secondary extirpation were done and in 3 cases biopsy only was done. There were no complications in 6 cases. In the seventh there was a hemiplegia which, however, disappeared in 2 weeks. Histological examination showed 5 cases of typical carotid tumor 1 case of fibroma and 1 of neuroma. There were no signs of malignancy in any of the cases. AUGUST G. MORGAN, M.D.

Rottino, A., and Howley, C. F.: Osteoid Sarcoma of the Breast; A Complication of Fibroadenoma. *Arch. Path., Chic.*, 1943 40 44.

The authors present a case report of an unusual tumor of the breast containing osteoid tissue. Their patient suffered from a rapidly growing neoplasm which recurred three months after it was removed and which caused death in ten months despite intense roentgen therapy.

Although the regional lymph nodes remained free, the lungs became seeded with metastases. One of the outstanding gross characteristics of this type of tumor was present in theirs namely, a large cyst filled with necrotic, hemorrhagic debris. The cyst had evidently developed through a process of necrosis and liquefaction of a portion of the tumor. Hemorrhage represented a late complication.

The tumor itself was abundantly cellular and the cells were polymorphic. Outstanding among these were numerous multinuclear giant cells. Another important finding in the case was osteoid tissue described in only 9 of the 25 cases assembled from the literature.

In 10 of the cases reported in the literature, fibroadenoma was observed in intimate association with the giant-cell tumor. In some cases there were only remnants of fibroadenoma. In a few others the main tumor was fibroadenoma and the osteoid and giant-cell phase of the growth was observed developing within it.

Stillings was the first to propose that the giant-cell tumor arose in the fibroadenoma. Many have since agreed with him including the authors. Granting this to be a fact namely that a stage of uncompleted fibroadenoma precedes the cancerous phase one can see a meaning to the clinical awareness of the tumors for twelve, nineteen and even thirty years

2 exceptions was 25 per kgm. of body weight. The amount of swelling was either comparable with or less than that found in Group II and in those experiments in which the ligatures were removed one hour after the trauma, there was little additional swelling apparent. This was indicative of early arrest of hemorrhage while the limb pressure was low. The systemic blood pressures were in some instances slightly to moderately reduced, but in no case did shock develop.

In those animals which were sacrificed from one and one tenth to three and one tenth hours after trauma the local fluid loss with a few exceptions was less than half that of control Group I, and was not enough to produce shock. The animals that were allowed to survive were in good condition the following day.

In Group I the rapid swelling of the limb and the large amount of local fluid loss (which at necropsy was found to be blood in very large measure) are evidence that factors other than hemorrhage did not play an important part in the production of shock and death. In Group II the animals were protected from shock through the action of the spinal anesthetic in blocking the vasomotor and (less important) motor nerves lowering the blood pressure, and reducing the hemorrhage below a level that produces shock. There was no evidence that blockage of nociceptive stimuli was an important factor in preventing shock. In Group III the trauma was greater than in Group I and as the nerves were intact, the flow of nociceptive stimuli should, therefore, have been as great as or greater than in Group I. Still shock did not develop.

There is no evidence in these experiments of an important action from toxins formed in the damaged tissues since, if present, it should have been manifest in Groups II and III in which the trauma was greater than in Group I. In the animals in Group I the onset of shock was too rapid to have been caused by toxins.

Swingle and coworkers confirmed the work of others that section of the nerves to the limbs or of the spinal cord at the thirteenth thoracic or first lumbar vertebra does not prevent shock from limb trauma. This would preclude the possibility that any protection obtained from procaine injections of the nerves or tissues was the result of blockage of nociceptive stimuli from the traumatized regions. The theory that the descending tracts of the ventromedial areas of the cord protect against limb-trauma shock, but that afferent nociceptive stimuli from the legs, apparently transmitted by the ventrolateral cord regions, eliminate this factor and sensitize to shock, was tested experimentally as follows: the left dorsal spinal nerve roots below the twelfth thoracic vertebra were sectioned, which destroyed all afferent impulses from the left limb. When the limb was subsequently traumatized there was no sign of protection against shock, as the animals tolerated blood loss and tissue damage no better than did the normal dogs of Group I.

Joux L. Laroque M.D.

Phemister D. B., Eichelberger L., and Laester C. H.: Early Effects on Dogs of Section of the Eighth Cervical Segment of the Spinal Cord and Their Bearing on Shock. *Arch. Surg.* 945 51 J

Since it has been considered that nervous factors may play an important part in the production of surgical shock by lowering the blood pressure and impairing the circulation, it should be of interest to study the physiological morphological and biochemical reactions in animals in which the blood pressure is lowered by the alteration in nervous function which follows section of the eighth cervical segment of the spinal cord.

The most immediate general effects are motor and sensory paralysis distal to the level of section and vasomotor paralysis complete except for the vasodilator fibers to the chorda tympani and glossopharyngeal nerves and the antidromic pathways of the posterior roots of the cervical nerves. After a brief initial rise there follows a marked fall of blood pressure, a slowing of the pulse and respiration, a fall of the body temperature and a variable degree of depression or stupor which usually wears off within 24 hours. The excitability of all somatic, vascular, and visceral reflexes posterior to the section is diminished. This early state of the animal was defined by Sherrington as spinal shock.

The most widely accepted theory as to the cause of the fall in blood pressure following section of the spinal cord at the eighth cervical vertebra is that interruption of the pathways to the sympathetic nervous system cuts off vasoconstrictor impulses coming from the higher centers. Diminution of respiratory movements by paralysis of the intercostal muscles and of intra-abdominal tension by paralysis of the muscles of the abdominal wall contributes somewhat to the hypotension. It has also been maintained that the flaccid paralysis of skeletal muscles from the interruption of motor pathways results in dilatation of the capillaries venules and veins and that the subsequent pooling of blood from lack of extravascular muscular support is an important contributing factor to the lowering of the blood pressure and the impairment of the general circulation. This theory is contradicted by the decided fall in blood pressure which results from inhibition of the vasoconstrictors produced by stimulation of the depressor nerves and there is still doubt as to the degree of its importance.

The state of pronounced general depression and low blood pressure known as spinal shock, which follows section of the eighth cervical segment of the spinal cord in dogs does not lead to surgical shock if the animals are given adequate fluids food, and nursing care. The general depression gradually decreases while the blood pressure persists at the upper limits of the shock level for from 4 to 6 days before the onset of a slow, gradual elevation to preoperative levels. During this acute period of vasodepression there is additional evidence of impairment of the circulation, as shown by a moderate to severe reduc-

tion in the erythrocytes hemoglobin, and red cell volume. Limited studies indicate a slight reduction in the total blood volume. There is also a significant reduction in the serum protein and the oxygen and carbon dioxide content of the blood. Changes in the water chloride and sodium concentrations are small. Calcium concentrations are reduced, while potassium concentrations show a noticeable rise. The most important cause of these changes appears to be the trapping of erythrocytes in the tissues under conditions of vasodilation and low blood pressure.

When after section of the cord the animals were kept in the dorsal position on the operating table with wounds in each thigh for the insertion of cannulas in the femoral arteries and fluids and food were withheld, they reacted the same as the other group of animals during the first 6 to 12 hours. Thereafter the general depression began to increase and the blood pressure declined usually to very low levels where it remained for from 12 to 24 hours with the animals in a state of shock until death occurred. The hematological changes were similar to those of the earlier period of the first mentioned group except that there was a terminal trend toward hemoconcentration. Necropsy revealed evidence of acute degenerative changes in some of the tissues which were interpreted as being due primarily to anoxia.

In both types of experiments the animals were definitely more resistant to low blood pressure than has been found to be the case with animals in which the blood pressure was reduced to equally low levels by hemorrhage or local loss of fluid from injury. This is interpreted as being due to the fact that after the section of the cord there are vasodilation and better nutrition of the tissues than is the case after straight hemorrhage or the local loss of fluids from an injury with low blood pressure in which there is vasoconstriction. The observations support the view that a low blood pressure produced by the exclusion of vasoconstrictor activity whether from direct injury of the pathways or from reflex inhibition, causes less impairment of the circulation and less tendency toward shock than does an equally low blood pressure produced by hemorrhage or by local loss of fluid from injury. The administration of adequate amounts of water, electrolytes and food protects against circulatory failure when the blood pressure is at a low level as a result of the exclusion of vasoconstrictor activity by a spinal cord injury.

BENJAMIN GOLDMAN, M.D.

Mahoney, E. B., Howland, J. W., and Yackel, K.
The Role of Infection in Shock Produced by Muscle Injury. *Surgery* 1945 17: 803

Shock was produced in dogs by means of the Black crusher. The inoculation of virulent cultures of the streptococcus hemolyticus and the clostridium welchii into the thigh muscles just before application of the crusher modified the resulting shock. The survival time of animals inoculated with the former organism was two hours less than that of the control animals and of those inoculated

with the latter organism it was three hours less than that of the controls. The staphylococcus aureus injected into the thigh muscles before injury did not alter the survival time under the conditions of these experiments.

There was no greater fluid loss in the infected animals than in the controls and the decreased survival time was considered to be due to the infection of traumatized muscle and to circulating bacterial toxins. The infected animals did not have a secondary rise in blood pressure following the primary fall.

JOSEPH GARTER, M.D.

MEDICAL JURISPRUDENCE

Bloomfield, J. J.: Labor Management Relations.
J Am M Ass 1945 128: 639

Industrial hygiene as a science and as a public health service has been developed with the objective of protecting and promoting the health of the working population in an industrial system. Governmental agencies have taken action in solving industrial health problems because such action is a proper obligation of public agencies. Management has co-operated partly because of the necessity of the requirements imposed by certain types of work men's compensation acts and partly because management has gradually realized that there are other phases of the problem in need of attention. It has already begun to extend its surgical treatment work into such functions as pre-employment and periodic physical examinations, and in recent years into medical and engineering control of occupational diseases and job placement. Finally at present attention is being devoted to such problems as general illness among workers and to such factors as fatigue, dental hygiene, nutrition, mental health and similar adult health problems. Labor as represented by both organized and unorganized workers has had a lesser role in this development, largely because strong organization is necessary for effective action, and until recently unions have not been well enough established to allow them to give attention to the advancement of special welfare programs.

There is no reason, however, why labor cannot accomplish tasks in relation to the social front as it has already done through years of hard work on the political front. It will probably not be necessary for labor to go through as long a period of self-education as did management, since many of the patterns in this field of effort have already been developed, however the labor front should go slowly and recognize that it has a good deal to learn in the field of industrial health. Labor will find official and non-official health agencies ready to assist it in this educational process.

Co-operation between labor and management appears still to be in its infancy, more education in the technique of co-operation is needed for both industry and the unions. Labor-management committees sponsored by the War Production Board have served a useful function in stepping up pro-

duction for the war effort however when they have functioned in the permanent health and welfare activities the results have not been impressive. Attention to workers' health has been perfunctory, new opportunities for the improvement of working conditions and the worker's health have not been explored extensively by the labor management committees. In fact, Robert Watt, labor member of the War Labor Board believes that collective bargaining under the Board itself has served already to accomplish far more than these committees can do. The Board itself as distinguished from its committees being the best demonstration of the value of economic democracy. It is true, of course that the union agreement between management and labor negotiated through collective bargaining (as sponsored by the War Labor Board) offers one channel for the improvement of industrial health and working conditions. Health and safety provisions are specified in a number of existing contracts, however a study of the health and safety clauses shows that these provisions have been made in order to protect workers from unfair application of company reg-

ulations to right some specific grievance or to correct some single outstanding hazard. As far as can be determined, no union agreement provides for a broad industrial health program in the industry concerned with a view to long term reduction of sickness and the promotion of positive health.

All in all the major health problems of the working population cannot be solved by union agreements or by management or by labor alone.

A comprehensive national health program administered by state and local governments would meet the needs of all groups for health and medical service, hospital care and prevention of disease. It would be far more desirable to revise and strengthen our present laws on health and safety requirements, and especially their enforcement provisions. In such manner benefits of such laws could be applied to all workers rather than to those who happen to be strong enough to obtain concessions through contracts. Through such collective action on the legislative front the rights of neither management nor labor nor their free functioning will be impaired.

Operative Closure of Patent Ductus Arteriosus—Alfred Blalock

SURGERY

GYNECOLOGY AND OBSTETRICS

An International Magazine, Published Monthly

VOLUME 82

FEBRUARY, 1946

NUMBER 2

OPERATIVE CLOSURE OF THE PATENT DUCTUS ARTERIOSUS

ALFRED BLALOCK M.D. F.A.C.S. Baltimore Maryland

ALTHOUGH a procedure for closure of the patent ductus arteriosus had been described by Munro in 1907 and although the operation had been attempted by Strieder (1) the first successful closure of an open ductus was performed by Gross (3) in 1938. The first method used by Gross was that of simple ligation of the ductus. It is well known that the lumen of a large artery which is closed by ligation in continuity may become patent again as the ligature cuts through the wall. Gross abandoned the method of simple ligation after having used it on 14 patients because there was evidence that the occlusion did not remain complete in several patients. More consistent closure of the ductus was obtained by Gross in 28 patients by the use of a second method in which the ductus was ligated and was also surrounded by cellophane. Some recurrences developed after this procedure and these led Gross (2) to develop a third method which consists of complete division and closure of the ductus. This procedure had been used on 14 patients at the time of the last report and the results were satisfactory.

It is because I question the necessity and safety of performing an operation in which the ductus is cut across and the ends closed

that this brief communication is presented.

During a period of slightly less than 3 years my associates and I have operated upon 19 patients with patent ductus arteriosus most of whom were referred by Dr. Helen Taussig. There have been no serious accidents during the operations and no postoperative deaths in the hospital. Two of the 6 patients who had a *Streptococcus viridans* infection died subsequent to discharge from the hospital. There was definite evidence in only 1 patient that the lumen of the ductus became re-established following the initial closure. Two ligatures of braided silk were used in closing the ductus of this patient. It was noted at the time of operation that the ductus was quite short and that the ligatures overlay each other. Following the development of evidence that the ductus had reopened a second closure was performed. This patient had a *Streptococcus viridans* infection and she died 3½ months following the second operation.

We have used a number of different methods in our small series of cases. It is difficult to compare the effectiveness of the different methods because there has been evidence in only the 1 case referred to that the lumen of the ductus became re-established. In the earlier cases we used two ligatures of braided silk with or without an additional ligature of

From the Department of Surgery of The Johns Hopkins University and Hospital.

umbilical tape. In 2 patients the recent method of Gross (2) was modified to the extent that pursestring sutures of silk were placed at the extreme ends of the ductus. These were tied loosely and two straight clamps were placed on the ductus between the pursestring sutures. The ductus was divided between the clamps and the ends were closed with suture ligatures. Although no difficulty was encountered it was felt that the division of the ductus probably exposed the patient to unnecessary danger of severe hemorrhage. We then adopted the method which has been employed in 7 patients and which is used at the present time. The entire length of the ductus is carefully dissected free of the adjacent structures. Pursestring sutures of medium silk on French needles are placed at the two extreme ends of the ductus. The adventitia is caught in the suture in several places. These sutures are tied loosely yet sufficiently tightly to abolish the flow of blood through the ductus. Two through and through mattress sutures of silk are placed and tied between the two purse-

string sutures. A ligature of umbilical tape is then tied over the mattress sutures of silk. The method is shown diagrammatically in Figure 1.

There has been no evidence in the patients in whom this method has been used that the lumen of the ductus has become re-established. If subsequent experience corroborates this impression, it would seem that the method is preferable to that of division of the ductus because it subjects the patient to less danger of fatal hemorrhage. Even if division and closure of the ductus proves to be the method of choice it would seem that the procedure can be made less dangerous by the preliminary placing of pursestring sutures at the extreme ends of the ductus.

Fig. Blood amylase activity as measured by cuprous oxide precipitation. A soluble starch is used. To measure decreased blood amylase activity it is advisable to use more sensitive starch. Row A. Tube 1 is normal control with a very small amount of light brown cuprous oxide precipitate uniformly distributed on the bottom. This may sometimes come down as a very slender yellow ring.

Tube 2, Case 75835, group 1 is read as normal though a trifle more precipitate appears in it than in the control. The test was done during an attack of cholangitis. It was repeated twice and found normal on both occasions.

Tube 3, Case 73 96, group 5 or Case 3 Table I, with blood amylase activity markedly increased. Acute hemorrhagic pancreatitis found at necropsy (see Fig. 1).

Tube 4, Case 73 65, group 1 or Case 3 Table I with blood amylase activity normal. Chronic pancreatitis found at operation. This patient recovered. Row B. The bottoms of tubes in Row A. Row C. Variations in the rings or bottoms of precipitates obtained with soluble starch. When the more sensitive starch is used this is the type of precipitate one is apt to get with the normal control.

BLOOD AMYLASE ACTIVITY IN PANCREATITIS AND OTHER DISEASES

A Simple Diagnostic Aid

DAVID POLOWE M.D. F.A.C.S. Paterson New Jersey

IT is the purpose of this article to call attention to the evaluation of blood amylase activity in pancreatitis and other diseases and to a simple diagnostic aid (16), which measures blood amylase activity in terms of cuprous oxide precipitation. The test is almost as simple as the determination of sugar in urine and it has now been used with increasing success for over 4 years.

This study is based on 78 blood amylase activity determinations in 69 patients. In 62 patients the diagnoses were proved by acceptable criteria such as necropsy, operation, biopsy, x-ray, laboratory, or combinations of these. Though in 7 patients the diagnoses were unproved, the cases have been included in this series for the more conservative statistical evaluation of the incidence of proved pancreatic disease. In 63 patients the tests were run to rule in or to rule out acute pancreatitis, carcinoma of the pancreas, or to determine the blood amylase activity in biliary tract and other diseases. And the test was run in one case of pancreatic collection (pseudocyst) which was observed at the Newark City Hospital; the complete report of which is included in this series through the courtesy of Dr. R. O. Bauman.

CASE REPORTS

In this series of 69 cases there were 6 cases of acute pancreatitis proved at operation or at necropsy. The case of pancreatic collection was proved at operation. Because of its clinical importance, a case of mesenteric and portal vein thrombosis associated with a marked blood amylase activity is also reported.

CASE 1: History No. 73165. M. L. female, white, aged 45 years, housewife, was admitted to the hospital May 15, 1943.

From the General Surgical Service, Barnert Hospital, Paterson, New Jersey, and the Thoracic Service, Bergen Pines Hospital, Ridgewood, New Jersey.

About 1 month prior to admission the patient suffered indigestion. She vomited after breakfast and had severe pain over the entire lower abdomen. The attack was accompanied by belching, a bitter taste, and pain which radiated to the back and to the shoulder blades. She gave a history of previous attacks of a similar nature.

On physical examination a marked enlargement of the abdomen was noted. A smooth, hard mass was felt in the pelvic region below the umbilicus. This mass was movable and not tender. There was marked distention in the epigastrium and tenderness over the gall bladder region. However, the gall bladder could not be felt.

In the left upper abdomen there was a mass just below the left costal border which extended backward toward the kidney. There was tenderness in the left costovertebral angle. This mass felt more like the kidney than the spleen. It was thought that free fluid was in the peritoneal cavity. Moderate icterus was present.

Laboratory examinations of blood May 15, 1943, showed: icterus index 35, hemoglobin 12 grams per cent, red blood cells 4,440,000, white blood cells 21,200 with large mononuclear leukocytes 4 per cent, lymphocytes 6 per cent, eosinophils none, band forms 9 per cent, polymorphonuclear leukocytes 81 per cent. Examination of the urine showed specific gravity 1.013, a trace of albumin, no sugar, no acetone. On microscopic examination there were found a few white blood cells, an occasional red blood cell, no casts.

On May 18, 1943, 3 days after admission, a blood amylase activity test was performed and found to be normal (2 plus) (see Fig. 1, row A, tube 4).

On May 27, 1943, 12 days after admission, a supracervical hysterectomy was performed. At operation the gross findings were those of a large uterus with intramural fibromyomas, cholelithiasis, free fluid in the peritoneal cavity, and fat necrosis in the area of the pancreas.

On June 10, 1943, the patient was discharged, recovered. She was readmitted in August, 1943, and on August 23, 1943, a cholecystectomy was performed and the patient was subsequently discharged, recovered.

Pancreatitis as a cause for this patient's chief complaints was definitely considered prior to operation. The blood amylase activity test was found to be normal. It is a known

fact that blood amylase activity rises sharply at the onset of an attack of acute pancreatitis and may subside just as sharply within 72 hours of the onset. For that reason one should not sacrifice the judgment gained by years of clinical experience for a noncorroborative diagnostic laboratory aid. Briefly a normal blood amylase activity report does not rule out the presence of acute pancreatitis whereas a moderately or markedly increased blood amylase activity rules strongly in favor of acute pancreatitis.

Attention is invited to the fact that the patient was observed for 12 days prior to the first operation when the pelvic pathological lesion was removed. The initial symptoms had subsided, the patient was in good condition for operation, all thoughts of acute pancreatitis had vanished in the light of the normal blood amylase activity so that the presence of fat necrosis in the area of the pancreas came as a mild surprise.

CASE 2. History No 72105 D V, female white, aged 53 years, was admitted to the hospital March 20, 1943, with a chief complaint of pain in the epigastrium of 6 months duration. The pain was more severe after she ate heavy food and was occasionally associated with vomiting. In the past 3 months the epigastric pain was much more severe and came more often. She had lost 10 pounds (4.5 kgm.) of weight in the past 3 months. The epigastric pain had been very severe for the past 10 days.

On physical examination there was found a definite tenderness in the epigastrium and right upper quadrant of the abdomen. A mass was palpable in the gall-bladder region and it extended two fingers below the costal margin. The temperature was 100 degrees (37.2 C.), pulse 68, regular, blood pressure 130 millimeters of mercury systolic, 80 millimeters of mercury diastolic.

Laboratory examination of urine showed specific gravity 1.020, albumin, a trace, no sugar, acetone a trace. Examination of the blood showed hemoglobin 3 grams per cent, red blood cells 3,600,000, white blood cells 7,900 with large mononuclear leukocytes 2 per cent, lymphocytes 14 per cent, eosinophils 1 per cent, polymorphonuclear leukocytes 83 per cent.

Clinical impression: acute cholecystitis. On March 23, 1943, 3 days after admission, operation was performed. A hemorrhagic pancreatitis with fat necrosis, cholecystitis and cholelithiasis were found. Cholecystostomy, removal of gall stones and drainage were done.

The pathologic report (by Lt. J. Churg) (1) Portion of gall bladder wall showed edema and chronic inflammation. (2) cholelithiasis. (3) portion of fat tissue showed small areas of necrosis.

The blood amylase activity test was performed 5 days after the operation and was moderately (3 plus) increased. The patient was not relieved by the operation. She became depressed, continued to vomit and finally expired on May 1, 1943, 39 days after the operation.

Since only one blood amylase activity test was performed we are left in the dark as to the changes that took place in the pancreas from a secretory point of view. There was no necropsy so we do not know the exact cause of death. We were left with the impression that a moderate blood amylase activity increase may be associated with a serious prognosis in acute pancreatitis. This case also emphasized the fact that blood amylase activity tests should be run every day or every other day since it is known that blood amylase activity usually parallels the course and the clinical symptoms of pancreatitis (10).

CASE 3. History No 73106, J. J. male, aged 60 years, was admitted to the hospital May 17, 1943, and died May 19, 1943.

His chief complaint was severe abdominal pain and vomiting. The onset occurred on May 13, 1943, with pain in the precordium which extended down the left arm. This recurred the following day, May 14, 1943. On May 17, 1943, the patient was seized with severe pain in the upper abdomen followed by continuous vomiting. The patient then developed severe shock associated with a subnormal temperature and a cold, clammy skin.

The patient had had an attack of severe abdominal pain followed by nausea and vomiting in October, 1941. At that time there was some tenderness over the abdomen but no rigidity.

Physical examination revealed a soft, distended abdomen, with no areas of rigidity but tenderness was present on pressure and rebound.

Laboratory examinations revealed white blood cells at 500 with a marked shift to the left. The blood amylase activity was markedly increased (4 plus) (see Fig. 1, row A, tube No. 3).

The patient went rapidly downhill with a rising temperature. He died 48 hours after admission.

The pathologic diagnosis (necropsy by Lt. J. Churg) was as follows: acute hemorrhagic pancreatitis, widespread peritoneal and retroperitoneal fat necrosis, periesophageal fat necrosis, hemorrhagic effusion in the peritoneum (800 c.c.) and in both pleural spaces (200 c.c.), chronic cholecystitis and cholelithiasis, pulmonary emphysema, atelectasis of both lower lobes, pulmonary edema and congestion, arteriosclerosis of the kidneys.

Acute hemorrhagic pancreatitis was the cause of death but coronary thrombosis was the foremost clinical diagnosis in the minds

Fig. 1. Gross specimen of Case 73190 group 5 or Case 3, Table I. The under surface of the liver, the gall bladder and the stomach are turned up. The pancreas has been cut transversely and opened like a book. The acute hemorrhagic process can be seen in the body and the tail of the pancreas. There were numerous plaques of fat necrosis in the head and tail of the pancreas as well as in the peritoneal and retroperitoneal structures.

of the attending physicians for 3 days prior to admission of the patient to the hospital when the clinical state of the patient was that of epigastric pain and vomiting. A diagnosis of acute hemorrhagic pancreatitis was then made and confirmed first by the *marked increase (4 plus) in blood amylase activity* and then by necropsy (Fig. 2).

CASE 4. History No 76645 S. E. male white aged 44 years was admitted to the hospital February 28 1944 with a chief complaint of severe epigastric pain followed by nausea and vomiting. The present illness began 2 days prior to admission. In September 1943 the patient had suffered a severe attack of epigastric pain associated with severe vomiting and nausea. There was no jaundice and the pain radiated to the right shoulder. The pain started suddenly and stopped suddenly. The patient was well for 3 weeks and then had a repetition of the symptoms named. In October 1943 an x-ray series revealed the presence of stones in the gall bladder. Shortly after this the patient suffered another attack of severe epigastric pain. He was placed on a strict diet and was free from pain until 2 days prior to admission on February 28 1944.

On physical examination the patient appeared to be acutely ill. There was no clinical icterus. The abdomen was distended and there was an a

lated marked rigidity and exquisite tenderness in the right upper quadrant of the abdomen over the gall-bladder region. There was no tenderness in the costovertebral angles. The temperature was 90 degrees (37.2 C) the pulse 94 respirations 18.

Laboratory examination of the urine revealed reaction acid specific gravity 1.030 albumin a trace sugar 3 plus acetone negative. On microscopic examination a few white blood cells were found but no red blood cells no casts or bacteria were present. Blood count showed white blood cell 18,500 hemoglobin 17.0 grams per cent red blood cell 5,500,000.

Clinical impression acute cholecystitis with cholelithiasis.

Cholecystectomy and choledochotomy were performed on the day of admission February 28 1944. A large amount of bloody fluid was present in the peritoneal cavity. There was hemorrhage into the pancreas. Fat necrosis of the pancreas was present, and a large number of stones were found in the gall bladder. The common duct was dilated but no stones were found in it.

March 1 1944 2 days after the operation a blood amylase activity test was performed and reported markedly increased (4 plus).

Pathologic diagnosis (Dr A. J. Giltz) acute cholecystitis with prominent acute petechial hemorrhage into the omentum fat showing areas of fat necrosis and in specific acute inflammation chronic cholecystitis.

TABLE I.—SUMMARY OF 6 CASES OF PANCREATITIS PROVED AT OPERATION OR AT NECROPSY

Case No.	History No.	Diagnosis and remarks	Blood amylase activity
	71405	Chronic pancreatitis, cholecystitis, cholelithiasis. Operation 3-12-43. Cholecystectomy. Died 3-1-43.	3 plus. Test done 3 days postoperative
	71185	Chronic pancreatitis, cholecystitis, cholelithiasis, Strumoma testis. First operation 3-17-41, hysterectomy. Discharged, recovered, 6-10-41. Second operation 8-12-41, cholecystectomy. Discharged, recovered.	plus (normal). Test done 6 days prior to first operation
3	73196	Acute hemorrhagic pancreatitis, chronic cholecystitis, cholelithiasis. Admitted 2-7-42. Died 3-19-42. Necropsy	4 plus. Test done the day of admission
4	76643	Acute hemorrhagic pancreatitis, chronic cholecystitis, cholelithiasis. Operation 2-28-42, cholecystectomy and cholecystectomy. Discharged 3-27-42, recovered	4 plus. Test done 3 days postoperative
5	79813	Acute hemorrhagic pancreatitis, chronic cholecystitis, cholelithiasis. Admitted 11-17-44. Operation 1-19-45, Strumectomy. Died -10-44. Necropsy	3 plus. Test done the day before operation
6	82077	Acute pancreatitis (pancreas indurated, nodular associated with fat necrosis). Cholecystectomy performed 16 yr prior to present admission. Admitted 2-22-45. Operation 3-27-45, cholecystectomy. Discharged 6-28-45, recovered	3 plus. Test done 3 days after admission. 14 plus 3 days later, associated with clinical improvement, 3 days prior to operation

On admission the patient was in no distress. She was well developed, well nourished, and exhibited no rashes or icterus. The positive findings were as follows: blood pressure 130 millimeters mercury systolic, 90 millimeters mercury diastolic. In the left upper quadrant of the abdomen there was a mass about the size of a grapefruit which protruded only slightly above the abdominal contour. This mass extended into the epigastrium where it was tender. The possibility of two masses was considered.

Provisional diagnosis malignant growth of the stomach splenomegaly of unknown etiology.

Retrograde pyelography disclosed no pathological process. Cystoscopy disclosed none. Peritoneoscopy revealed a mass in lesser omental cavity perhaps a cyst of the pancreas the stomach displaced anteriorly. X-ray (barium enema) examination revealed evidence of pressure at distal third of transverse colon and splenic flexure probably due to extrinsic pressure. Chest examination revealed left diaphragm flat and slightly elevated. Thoracic and lumbar vertebrae showed no evidence of the presence of pathology.

Laboratory examination of the urine revealed albumin, 2 plus, concentration good. Examination of feces for undigested fats gave normal findings. Blood chemistry examination revealed normal values for sugar, urea, nonprotein nitrogen, and creatinin. White blood count showed 9,150 polymorphonuclear leucocytes 64 per cent. Red blood cells numbered 3,000,000 to 4,000,000 hemoglobin range was 56 to 60 per cent.

The size of the mass fluctuated slightly, and its tenderness was intermittent. On the fourth day of admission the patient awoke with severe substernal pain which did not radiate. This attack was accompanied by profuse diaphoresis. Dyspnea was experienced but no cyanosis was visible. There were no chest signs.

Clinical impression (1) possible small pulmonary embolus (2) possible coronary episode.

The abdomen continued to be painful and the patient was brought to surgery. A left rectus incision revealed a fluctuant mass above and behind the stomach. The foramen of Winslow was closed. A nick was made in the gastrohepatic mesentery and the mass was drained of about 2000 cubic centimeters of brown, bile-stained or coffee-colored fluid with little odor. This sac was packed with plain gauze. The sac was marsupialized and the gauze was left hanging outside. The abdomen was closed in layers after a piece of the sac wall was excised for biopsy.

The postoperative course was uneventful. The cavity continued to drain small amounts of coffee-colored fluid. The drain was ultimately removed and the patient was discharged, 5 weeks after admission.

A biopsy specimen of the cyst wall revealed fibroblastic tissue. Organisms were not found. The blood amylase activity done several days after operation, by the cuprous oxide precipitation method (16) was found to be markedly increased (4 plus).

A letter from Dr. Richard O. Bauman, dated June 18, 1942 states "Enclosed is a summary of the case you were interested in. She is now discharged even though she has considerable drainage from the marsupialized sac or cyst."

"It was the opinion of some of the men on the staff that this lesion came under the group classified as pseudocysts of the pancreas. Biopsy of the cyst wall and other evidence such as a closed foramen of Winslow and the presence of old inflammatory fibrosis seem to substantiate this but then again, we could not be sure. A follow up is in order."

The patient could not be followed up further.

The increased blood amylase activity found in this case helped the staff lean toward a diagnosis of pseudocyst of the pancreas. Pinkham, in a review and analysis of 10 cases of pancreatic collections (pseudocysts) states

that "Persistent elevation of the serum amylase following the signs and symptoms of pancreatitis or pancreatic necrosis is significant, indicating the probable development of a pancreatic collection

Thus we are once again reminded that single blood amylase determinations while very valuable in the acute case are not as valuable as repeated determinations where the clinical diagnosis is in doubt and the condition of the patient permits study over a period of days prior to operation

ANALYSIS OF CASES

Group 1 Of the 69 patients tested 37 (53.6 per cent) were found to have a normal blood amylase activity. As we gained experience with the interpretation of blood amylase activity we discovered that a normal blood amylase activity is a true source of comfort. In only 1 instance (Case No. 73165 which is reported here in detail) was a proved pancreatitis found associated with a normal blood amylase activity and this patient recovered.

A white female, aged 60 years. Case No. 75446 was admitted to the hospital with a chief complaint of severe epigastric pain and vomiting. This was associated with an intense icterus. She had had a cholecystectomy 10 years before. A gastrointestinal x-ray series revealed the presence of a tiny herniation of the stomach through the diaphragm, a duodenal diverticulum, a shadow as of a stone in the region of the right kidney or gall-bladder bed. Consultations were held. A clinical diagnosis of common duct stone was made and it was desired to rule out an associated acute pancreatitis. The blood amylase activity was normal. A stone in the common bile duct was found at operation. The pancreas was not inflamed. A choledochotomy was performed, the stone was removed and the patient made an uneventful recovery.

Case No. 79776 illustrates the use of blood amylase activity determinations in the location of intestinal obstruction. In 1933 it was reported (15) that increased blood amylase activity may be found in high intestinal obstruction and in 1940 Johnson and Bockus reported an elevated serum lipase in intestinal obstruction. It is conceivable that pancreatic enzymes may be reabsorbed into the general circulation from severely distended small intestines before viability of their walls is lost.

In Case 79776 the diagnosis of intestinal obstruction was quite certain and the normal blood amylase activity not only served to rule out acute pancreatitis but made it seem likely that the obstruction was low. At operation the ileum was found twisted on itself and so adherent to the posterior peritoneal wall of the peritoneum in the right vertebral gutter that it could not be released without fear of tearing it. An ileostomy was performed. The patient died 12 hours later. At necropsy 5 days after the onset of the illness 1 foot of ileum was found gangrenous about 1 foot from the cecal end. This gangrenous loop of ileum was found firmly caught under a free edge of the root of the mesentery and explained the inability of the operator to free this 12 hours earlier.

Group 1 includes 3 patients with serious kidney pathology (cases Nos. 77219, 80353 and 82145) with carcinoma of the right kidney, left pyelitis cystica and uremia respectively. Since urine excreted by normally functioning kidneys has an amylase activity of 2 to 6 times that of blood many attempts have been made to correlate kidney function with blood amylase activity or urinary amylase activity. It is reasonable to expect a normal blood amylase activity in the first 2 cases mentioned because only one kidney was involved in each of these patients. In the third case in which the patient died of uremia one is at a loss to account for the normal blood amylase activity for with markedly diminished kidney function one does expect an increased blood amylase activity. However, the problem is not as simple as all that for it is conceivable that associated liver damage may be the responsible factor. Considerable study is required to correlate kidney function with blood and urinary amylase activity. Dozzi has concluded that there is no quantitative relationship between blood and urinary amylase.

Eleven patients with biliary tract disease appear in group 1. Since in our experience acute pancreatitis was found associated with biliary tract disease in all (100 per cent) of the 6 proved cases of acute pancreatitis a normal blood amylase activity in biliary tract disease has come to be regarded by us as safely excluding an associated acute pancreatitis or that a pre-existent acute pancreatitis is subsiding.

Group 2 In group 2 are 7 cases with decreased (1 plus) or absent (zero) blood amylase activity.

ase activity (10.1 per cent of the 69 patients observed) In this group the decrease was in no instance associated with acute pancreatitis.

The liver is considered by some observers, among them Dozzi to play some part at least in the formation of amylase. For that reason a decreased or absent blood amylase activity has been interpreted as evidence of unpaired liver function. Lewison has reported a depressed serum amylase in liver disease. Bartlett studied blood amylase activity in thyroid disease and concluded that a decreased blood amylase activity indicates impaired liver function in that condition.

A decreased or absent blood amylase activity may be found in any chronic, wasting disease such as tuberculosis (4 cases) or carcinoma (1 case). In tuberculosis amyloidosis of the liver is a common finding. In carcinoma of the stomach metastatic nodules may replace most of the normal liver tissue.

There were 2 cases of biliary tract disease in group 2—decreased (1 plus) or absent (0) blood amylase.

The first H. W., a white female, aged 68 years was admitted with a chief complaint of severe right upper abdominal pain. This pain was associated with an intense icterus. X-ray examination disclosed a nonfunctioning gall bladder. The laboratory reported a blood picture of severe pernicious anemia with a red blood cell count below two million. The blood amylase activity was decreased (1 plus). The patient improved remarkably under crude liver extract therapy and was discharged, improved. A year later she suffered another attack of gall-bladder colic and submitted to operation chronic cholecystitis and cholelithiasis were found cholecystectomy performed and the patient is alive and well today though she has to continue with liver extract therapy.

Since in Group 1 there were 2 cases of pernicious anemia (Nos. 72400 and 81248) and 11 cases of biliary tract disease one cannot be sure that pernicious anemia *per se* is responsible for the decreased blood amylase activity in the first case in group 2 (H. W.) nor that the biliary disease is responsible for the decreased blood amylase activity in both Case 1 H. W. and No. 74702 in group 2.

Suffice it to say that in the present state of our knowledge of decreased blood amylase activity one may safely regard such decrease as ruling out serious pancreatic disease. And

that while a decreased blood amylase activity may point toward decreased liver function one should use other and better known liver function tests when the function of the liver is under investigation.

Group 3. In group 3 there were 9 cases with slightly increased ($2\frac{1}{2}$ plus) blood amylase activity (13.1 per cent of the 69 patients observed). In none of these were we able to prove that acute pancreatitis was present. Several impressions were gained from a study of these cases of slightly increased blood amylase activity: (a) single determinations of blood amylase activity are not as valuable as repeated determinations; (b) a mild pancreatic edema accompanies such clinical entities as biliary tract disease, blockage of the lymphatic system and in pneumonitis secondary to cardiovascular disease; (c) that variations in blood amylase activity may be expected in thyroid disease.

Whenever a single determination of blood amylase activity is reported as slightly increased the test should be repeated every day or every other day. In a pancreatitis which is subsiding, remaining stationary or is getting worse there is usually a concomitant decreasing, stationary or increasing blood amylase activity. This statement is based not only upon my own experience but also upon the experience of others notably McCorkle, Goldman and Cornell who made 909 blood amylase activity determinations in 48 cases using the method of Somogyi. They state: "Serum amylase usually parallels the course of the disease and clinical symptoms though the latter may clear before the blood amylase is normal."

When the biliary tract is involved as in Cases 73289, 73303 and 80219 we are no longer surprised to find a slight increase in blood amylase activity since in all 6 of our proved cases of acute pancreatitis there was associated biliary tract disease. This also brings up the question as to whether biliary tract disease causes acute pancreatitis or whether chronic pancreatitis causes biliary tract disease. Weiner analyzed 4000 necropsies and found that "The incidence of gall-bladder disease is significantly increased in pancreatitis but the incidence of pancreatitis in

gall-bladder disease is only slightly if at all higher than in the general autopsy series. Colp, Gerber, and Doubillet state that cholecystitis may be due to pancreatic reflux, and Wolfer has found that pancreatic juice may be the etiologic factor in the production of cholecystitis in the dog. Weiner was able to show that a common channel may exist between the common bile duct and the pancreatic duct without the development of acute hemorrhagic pancreatitis. Our pathologist Dr. A. J. Githitz states that reflux bile *per se* is not always a cause for pancreatitis. In the 2 of our 6 proved cases of acute pancreatitis which came to necropsy no bile was found in the pancreatic ducts and Dr. Githitz states that he has examined postmortem at least 3 other cases of acute hemorrhagic pancreatitis in which no bile was found in the pancreatic ducts.

Dragstedt, Haymond and Ellis have shown that in 60 per cent of the cases of acute hemorrhagic pancreatitis, there was an antecedent biliary tract disease. In 10 per cent of these a common channel was produced by the impaction of gall stones in the ampulla of Vater. In the majority of the remainder, a common channel was produced by spasm of the sphincter of Oddi or edema of the papilla. They state that in cases in which bile is not the etiologic factor then concentration of the alkali of pancreatic juice is the destructive factor just as concentration of acid in the gastrum may be the destructive factor in that location.

Thus a study of the literature makes it apparent that both the 'common channel theory' of bile reflux and the obstructive theory with its concomitant concentration of the alkaline pancreatic juices within the pancreas are both tenable etiologic factors in the production of acute pancreatitis. And the pancreatic reflux theory is a plausible explanation for the high incidence of cholecystitis in pancreatic disease. When these theories are understood and reflected upon, it becomes easier for the clinician to interpret blood amylase activity in biliary tract disease and the need for repeated blood amylase activity determinations in the borderline case becomes more apparent.

Blockage of the lymphatic system may cause an increase in blood amylase activity. In case No. 73653 in which there was a mesenteric cyst about 15 centimeters in diameter and in case No. 74118 in which there were retroperitoneal metastases from an embryonal cell carcinoma of the testes a slightly increased blood amylase activity was found. The mechanism of this increase in blood amylase activity cannot be explained entirely. Shafiroff, Price and Polowe cited by Polowe (14) ligated the thoracic duct and the common bile duct in 1 dog (dog 4). There was an immediate rise in blood amylase activity and this rise was sustained for 48 hours when the dog died. One can only speculate as to whether the ligation of either duct alone would produce this result or whether it takes both conditions combined to do so. The impression at present is that since the lymphatic system is in close communication with the venous system throughout the body lymph with its accompanying enzymes backs up into the general venous circulation when the lymphatics are blocked.

Popper and Necheles cannulated the thoracic ducts in 3 dogs and occluded the portal vein in a 4th dog. They damaged the pancreas in these dogs by the injection of 0.1 to 4 cubic centimeters of bile into the pancreatic duct. They then determined the amylase and lipase activity in the peripheral blood, the portal blood and the lymph. They concluded that the main pathway of pancreatic enzymes into the peripheral blood following injury to the pancreas is by way of the portal vein and to a lesser extent by inflow of enzymes by the lymph of the thoracic duct. Their findings are corroborated clinically by cases Nos. 73653 and 74118 and the slight increased blood amylase activity found with blockage of the lymphatic system and case No. 76131 with superior mesenteric vein and portal vein thrombosis (reported in detail in the fore part of this paper) and its accompanying marked increase in blood amylase activity.

From the foregoing one can readily understand how necessary it is to study the history and clinical findings in each case in order to evaluate properly the blood amylase activity found.

There were 2 cases of pneumonitis secondary to serious cardiovascular disease in group 3. These were Case D M and No 80232.

Case D M a well known surgeon in our community became ill suddenly in 1941. The principal manifestations were pain in the right chest, severe epigastric pain, nausea and vomiting. The patient had had some form of intestinal surgery several years before and this was followed by an incisional hernia. Consultations were held. Roentgenograms of the chest disclosed a right lower lobe pneumonitis. The attending physicians thought that he might be suffering from either high intestinal obstruction or acute pancreatitis. A blood amylase activity test was ordered. Especial care was used in this instance because it was our first serious case in which the cuprous oxide precipitation method was being tried. It was found to be slightly increased ($2\frac{1}{4}$ plus). It was my opinion, given at that time, that this finding was not compatible with an acute pancreatitis but could be compatible with either a pneumonitis or a high intestinal obstruction. The patient's symptoms cleared, and subsequently it was discovered that the patient had a thoracic aneurysm. The patient died suddenly 2 years later when the aneurysm ruptured.

Since acute pancreatitis may simulate coronary thrombosis case No 80232 merits attention.

The patient, a white male aged 52 years was admitted December 22, 1944, and expired January 6, 1945. There was no necropsy. The important manifestations were severe precordial and abdominal pain, dyspnea, pallor, abdominal distention. The final diagnosis was coronary thrombosis with myocardial infarction, but a progress note made the day before the patient died is of interest. January 5, 1945. The first impression was that of myocardial infarction in a heart that already had one incident of thrombosis several years ago. There are several inconsistencies to be explained: (1) Marked ileus (this was present throughout the entire illness and was refractory to treatment); (2) involvement of the upper lobes of both lungs when one expects the lower lobes to be involved in a heart case; (3) bizarre x-ray of the chest exhibiting multiple small deposits throughout both lungs; (4) thick bloody sputum from which were obtained pneumococcus type III, *Staphylococcus albus* and *Streptococcus hemolyticus*. The x-ray findings are not those of pneumonia or infarct, rather they suggest the possibility of carcinoma of the lungs.

It is my opinion that the slightly increased blood amylase activity in this case was due to the superimposed pneumonitis. Increased blood amylase activity in pneumonia has been reported (12, 14, 15). The mechanism is difficult to explain but the following factors

alone or in combination may act to produce this effect in pneumonia: (1) The pneumococcus capsule is a polysaccharide. It is conceivable that this substance which has been labelled 'SSS' (specific soluble substance) may call forth an added amount of amylase in the blood stream. I was unable to prove this (14). (2) There may be pressure by the congested lungs upon the thoracic lymph duct and this may increase the blood amylase activity. (3) The infection itself may involve other organs so that it is conceivable that in pneumonia we may have a mild pancreatic edema which in turn will increase blood amylase activity. The fact remains that in 2 of every 3 cases an increased blood amylase activity was found in pneumonia (14).

Case 79086 with a diagnosis of toxic nodular goiter and diabetes mellitus is of interest because Bartlett has reported a decreased blood amylase activity in thyrotoxicosis, and he believes that such a decrease is indicative of liver damage. This one case showed a slightly increased blood amylase activity, the test being run off with a water control (16) because of the associated diabetes mellitus. Among the many laboratory findings were two basal metabolic rates of plus 79 per cent and plus 92 per cent. Suffice it to state that I am not sure how wise it is to draw any conclusions from blood amylase activity in thyrotoxic disease. The experimental work of Cope and associates on dogs and rabbits produced variations in serum amylase which were not consistent.

Nothing can be said about case No 80300, a white female aged 56 who was admitted December 28, 1944, and who signed her own release January 5, 1945. Her important manifestations were diffuse vague abdominal pain, vomiting, tenderness over the entire abdomen without rigidity, more pronounced in the right hypochondrium. Her blood Wassermann was positive. Her blood amylase activity was slightly increased.

In summing up this analysis of the 9 cases of group 3 in which a slightly increased blood amylase activity was found it appears safe to state that the pancreas is only secondarily and mildly involved in certain clinical ent-

ties. In cases in which it is doubtful as to whether or not the pancreas represents the principal seat of pathology blood amylase activity determinations should be made repeatedly every day or every other day. Ordinarily a careful analysis of the clinical and laboratory findings will lead one to a correct diagnosis.

Group 4. In group 4 there were 7 cases with moderately increased (3 plus) blood amylase activity. These 7 cases represent 10.1 per cent of the 69 patients observed. In every one of the 7 cases the pancreas appeared to be involved. This was proved in 3 instances: case Nos. 72495, 79855, and 82077 which are reported in detail in the fore part of this paper. I was unable to trace Cases F, F and F S so I have considered them as not proved.

Case No. 79627 was studied carefully and a final diagnosis of duodenal ulcer proved by x-ray and other acceptable criteria, was made. Because of the close proximity of the duodenal lesion to the pancreas one should not be surprised to find pancreatitis associated with duodenal ulcer. This patient improved on conservative treatment and her blood amylase activity was then found to be normal. This case and case No. 78148 in group 5 tend to corroborate the findings of Probststein, Wheeler and Gray and those of Goyena and Cipolla who reported increased blood amylase activity in gastroduodenal ulcers. Probststein *et al.* found blood amylase activity normal or subnormal when the lesion was on the anterior wall of the stomach, moderately elevated when it was on the posterior wall of the stomach. They believe that such findings are of value in differentiating such lesions from acute pancreatitis. On the other hand Hinton found blood amylase activity determinations of little value in 40 cases of peptic ulcer and Lewison found the blood amylase activity elevated in only 2 of 25 cases of peptic ulcer.

Case No. 74866 a white male, aged 71 years, was admitted October 3, 1943 and discharged October 6, 1943, improved. The chief manifestations were severe abdominal cramps associated with diarrhea. The onset was sudden, at 2:00 a.m. October 1, 1943. He went to work but had to call a physician at 9:00 a.m. He was sent to the hospital for observation. There was no history of previous medical or surgical diseases. On physical examination his temperature

ranged between 101 and 103 degrees F (38.3-39.4° C). There was marked abdominal tenderness and spasticity in the epigastric and left hypochondriac areas. The clinical impression was acute pancreatitis or perforated viscus. X-ray examination of the abdomen revealed no evidence of intestinal obstruction or ruptured viscus. The blood amylase activity was moderately increased on October 2 (the day of admission), and it was again found moderately increased 3 days later. The patient improved on conservative therapy and was discharged October 6, 1943, 4 days after admission with a final clinical diagnosis of acute pancreatitis.

Of the 3 proved cases of pancreatitis (case Nos. 72495, 79855 and 82077) 2 died. We are thus left with the impression that a moderate increase in blood amylase activity may be associated with a serious prognosis. One should not be surprised that a greater blood amylase activity is not found in acute hemorrhagic pancreatitis. In case No. 79855 there was grossly no viable pancreatic tissue left. In case No. 73196 group 5 only the head of the pancreas exhibited viable pancreatic tissue (see Fig. 2).

The study of these 7 cases in group 4 has led me to believe that a moderate blood amylase activity is almost always associated with pancreatitis of serious import and should be so considered until proved otherwise.

Group 5. In group 5 there were 9 cases with markedly increased (3½ to 4 plus) blood amylase activity (13.1 per cent of the 69 patients observed). Four of these cases (Nos. 73196, 76131, 76645 and 364205) reported in detail in the fore part of this paper were proved at operation or at necropsy.

Case No. 74626 was a white male aged 57 years, who was admitted September 9, 1943 with a chief complaint of pain in the right upper quadrant associated with vomiting. He had had a cholecystectomy 1 year before and was well until the sudden onset of his present illness. His abdomen was very much distended and there were marked tenderness and spasticity in the right upper quadrant. A clinical diagnosis of intestinal obstruction was made. The patient signed his own release the same day but was readmitted the following day, September 10, 1943 with the same complaints plus intense icterus. Among the laboratory findings was found a marked increase in blood amylase activity. A diagnosis of acute pancreatitis was made and the patient improved under conservative therapy. Three days later his blood amylase activity was normal (2 plus). The following day, September 14, the blood amylase

activity was slightly increased. On September 17, the patient had another bout of abdominal pain and vomiting and on that day the *blood amylase activity* was found moderately (3 plus) increased. The patient improved again under conservative treatment and signed his own release on September 20, 1943.

This case demonstrated how well the blood amylase activity parallels the clinical course of acute pancreatitis. There is little doubt in my mind that this was a true case of acute pancreatitis though I have recorded it as an unproved case because operation was not performed and the pancreas, for that reason, was not actually visualized.

Case No. 7562: a white female, aged 66, was admitted December 1, 1943 and discharged December 23, 1943. Improved. Her chief complaint on admission was pain in the stomach for 2 weeks and vomiting for the past 3 days. With the onset of the abdominal pain she suffered a right-sided hemiplegia and developed a severe headache. Her past history disclosed that she had had an attack of gall-bladder colic 6 years before. Otherwise her health had been good. On physical examination her temperature was 100 degrees F (37.8° C.), pulse 108 respirations 24, blood pressure 180 millimeters mercury systolic, 80 millimeters mercury diastolic. Her abdomen was tender in the right upper quadrant. The liver could be palpated a handbreadth below the costal margin. Both lower extremities exhibited ulcers. The reflexes on the right side were hyperactive. The laboratory findings were as follows: Urine—specific gravity 1.019, albumin, negative, sugar 3 plus, a few white blood cells, no red blood cells, no casts, acetone, negative. Icterus index was 20, cholesterol 235 milligrams per cent, white blood cells 11,800, with polymorphonuclear leucocytes 76 per cent, lymphocytes 20 per cent, mononuclear leucocytes 4 per cent, blood sugar 210 milligrams per cent, *blood amylase activity* markedly (4 plus) increased. For one reason or another no attention was paid to the blood amylase activity and a clinical diagnosis was made of acute cholecystitis, mild apoplexy and diabetes mellitus. The patient was treated conservatively though the surgeon who was called in consultation recommended cholecystectomy, his diagnosis being cholecystitis. The patient was discharged, improved, without operation December 22, 1943.

In reviewing this case I cannot escape the impression that the patient's chief complaints were due in part at least, to acute pancreatitis. And I am forced to conclude that a marked degree of blood amylase activity increase is not necessarily related to a serious prognosis. The clinical status of the patient is a far better guide to prognosis.

Case No. 76140 is of interest because the blood amylase activity determinations were made twice on the 7th and 8th days *post operative* to see what it would show. On both occasions the *blood amylase activity* was markedly (3½ plus) increased. The operation was performed January 20, 1944 and consisted of a gastrectomy and splenectomy. The patient developed pneumonia and anuria and expired on January 28, 1944, 8 days after operation.

The patient in this case was a white male, aged 53 years, who had had stomach trouble for the previous 2 years and had lost 25 pounds (11.4 kgm.) in that time. His previous health had been good. The physical examination among other things disclosed a hard nodular mass in the epigastrium, a mitral systolic murmur and marked varicosities in the left popliteal fossa.

At operation the stomach had to be shaved away from the pancreas to which it was strongly adherent. Bleeding occurred at the lower pole of the spleen and it was deemed necessary to remove the spleen along with the stomach.

In reviewing this case one regrets that a blood amylase activity determination was not made prior to operation. So many possibilities present themselves in this case as a cause for the increased blood amylase activity after operation that any one or combination of the following factors could easily have been the responsible factor: (a) injury to the pancreas and spleen; (b) the postoperative pneumonia; (c) the anuria. There was no necropsy. The pathologic diagnosis (by Dr. A. J. Gitlitz) was infiltrating adenocolloid carcinoma of the stomach with carcinomatous lymphangitis and lymph node metastases, mild toxic splenitis.

The seventh case in group 5, a white male, aged 65, was admitted three times in 1944 (history Nos. 77790, 78099, and 79261). On first admission, May 27, 1944, the patient had an incarcerated right inguinal hernia, which was operated upon the same day and he was discharged, recovered, June 14, 1944. On second admission 4 days later, June 8, 1944, he came with a chief complaint of right upper quadrant pain and icterus. An electrocardiogram showed no evidence of a heart lesion and an x-ray film of heart and lungs revealed no lung pathology. The heart was considered normal in size and configuration. The *blood amylase activity* the day after this admission, June 10, 1944, was markedly (4 plus) increased. He was treated conservatively and discharged improved July 11, 1944 with a final diag-

nosis of acute pancreatitis. On third admission, September 24, 1944, a diagnosis of arteriosclerotic heart disease was made. He expired October 27, 1944. Roentgenograms of the chest after lipiodol injection showed no evidence of bronchiectasis. The right dome of the diaphragm was elevated and there was air between the liver and the diaphragm. Examination of the esophagus showed a filling defect at the level of the arch of the aorta and a dilatation proximal to this point. Below the filling defect there was a constriction and the barium trickled slowly past this area. Esophagoscopy was performed by Dr. L. Markowitz, and a portion of the lesion was obtained for biopsy October 24, 1944. The pathologic report was squamous cell carcinoma with pearl formation. The patient expired October 27, 1944. There was no necropsy.

It is my conviction that on the second admission of this patient the diagnosis was acute pancreatitis. I have not considered this a proved case because neither operation nor necropsy was performed and the pancreas for those reasons was not visualized. Once again we note that a marked blood amylase activity need not necessarily spell a serious prognosis with regard to acute pancreatitis. It is the clinical status of the patient, rather than the laboratory aid that is the surest guide to prognosis.

Case No. 78148 in group 5 a white male aged 64 years was admitted June 21, 1944, and discharged July 6, 1944, improved. His chief complaint was right upper quadrant pain which radiated to the left across the abdomen. The pain was of 8 weeks' duration. His temperature ranged between 98.6 and 100.6 degrees F (37.0 and 38.1 C.), pulse 68 to 100 respirations 20 to 24. The laboratory work up included the following: gastrointestinal x-ray revealed duodenal ulcer. The white blood cells numbered 14,050 with stab forms 6 per cent, polymorphonuclear leukocytes 60 per cent, lymphocytes 33 per cent, monocytes 1 per cent, hemoglobin was 16.5 grams per cent. Red blood cells numbered 5,200,000. Blood sugar was 500 milligrams per cent. Nonprotein nitrogen was 26 grams per cent. Urine showed specific gravity 1.045, albumin negative, sugar 3 plus acetone a trace, an occasional white blood cell, no red blood cells, casts none. The blood amylase activity was markedly (4 plus) increased. The patient was treated conservatively by means of a diabetic diet and the injection of protamine zinc insulin. He improved and was discharged July 6, 1944.

Since a water control (16) was not run when the blood amylase activity was determined it is not known how much of the cuprous oxide precipitation was due to the high blood sugar. Experience has taught that

a marked blood amylase activity in diabetic mellitus is not entirely due to the free blood sugar when the cuprous oxide precipitation method is used. In this case there was a proved duodenal ulcer and it is likely that the abdominal pain was due to a mild pancreatitis induced by the nearby duodenal lesion. However one can only speculate about this in this case since a water control was not run to determine how much of the cuprous oxide precipitation was due to the free blood sugar in this severe diabetic. Goyens and Cipolla and others have shown that there is an increased blood amylase activity in some cases of duodenal ulcer. Our 2 cases, case No. 79627 group 4 and case No. 78148 group 5 tend to corroborate these findings.

In summing up on group 5 the conclusion is arrived at that a marked blood amylase activity always indicates involvement of the pancreas but that it does not always indicate that the pancreas is the main seat of the pathology. The outstanding exceptions were in the case of superior mesenteric vein and portal vein thrombosis in duodenal ulcer and in carcinoma of the stomach where the lesion is on the posterior wall adherent to the pancreas. Of the 3 proved cases in which the pancreas was the main seat of the pathology only 1 died. We are thus reminded that a marked blood amylase activity in acute pancreatitis does not necessarily mean a serious prognosis.

In Table I 6 cases of pancreatitis proved at operation or at necropsy have been grouped in order to emphasize the fact that the introduction of a laboratory aid such as the cuprous oxide precipitation test for the determination of blood amylase is fraught with difficulties. In Cases 1 and 4 of this table the test was run after operation after the diagnosis was established. This sort of finding is always anticlimactic. In Case 2 a normal blood amylase activity was found and subsequent operation showed the presence of pancreatitis. This to say the least, is always disappointing in spite of the fact that it is well known that blood amylase tends to decrease to normal when pancreatitis is subsiding and does so rapidly.

In 3 cases the blood amylase activity was determined before operation or before nec

TABLE II—THE PRINCIPAL PATHOLOGY AND BLOOD AMYLASE ACTIVITY IN 69 CASES

Principal pathology	N of cases	Blood amylase activity		
		Normal	De-creased	In-creased

Fulmonary tuberculosis	1		4	
Miscellaneous	3			
Total	69	37	7	2
%	100	53.6	10	3.3

ropsy and in all 3 (cases Nos. 3, 5 and 6) pancreatitis was found.

Two conclusions have been drawn from this study: (1) When increased blood amylase activity is found pancreatitis should be deemed to exist unless proved otherwise; (2) If one is to make a correct diagnosis of pancreatitis before operation or before necropsy one must be pancreatic disease conscious.

In Table II are given the principal pathology and blood amylase activity in 69 patients. A study of this table has led to the conclusion that multiple pathology is the rule rather than the exception when pancreatitis is part of the picture. In 25 cases (36.3%) there was an increased blood amylase activity. In 7 cases (28% of the 25, 10% of the entire series of 69 cases) the pancreas was the principal seat of pathology as proved at operation or by necropsy.

In only 1 case (3.3%) of the 44 cases in which the blood amylase activity was normal or decreased was a proved pancreatitis found. Thus again I am forced to conclude that a normal or decreased blood amylase activity tends to rule out pancreatitis or that, when it is thought to be present then it is subsiding or has subsided. By the same token, when ever an increased blood amylase activity is found pancreatitis should be deemed to exist

unless proved otherwise. A careful evaluation of all the facts will most surely lead to a correct diagnosis.

In estimating the number of cases in which the test was used to include or exclude pancreatitis the 5 cases of tuberculosis and the 1 case of toxic nodular goiter were not counted. Thus there were 63 cases in which it was sought to include or exclude pancreatitis. Of these a clinical diagnosis of pancreatitis was made in 12 (19%) cases of which 7 (11%) were proved at the time of operation or necropsy.

This is significant. It implies that every patient with upper abdominal pain must be considered suspect with regard to pancreatitis. If one keeps pancreatitis in mind at least 11 proved cases of pancreatitis may be discovered in every 100 patients with upper abdominal pain. And the more cases of pancreatitis that are found the better will be our treatment the better will be our results.

Of the 6 proved cases of pancreatitis 3 patients (50%) died. Of these 2 cases were fulminating affairs. As one reviews the histories in these cases the impression is gained that time is lost in making an accurate diagnosis and that there is as yet no set plan of treatment which has been found uniformly effective. Reflection upon this leads me to suggest that a "pancreatitis team" be formed in each hospital to cope with this problem and that there be a central "pancreatitis registry" where all proved cases of pancreatitis could be filed and made available for study and evaluation of the manifold phases of this truly serious disease.

With the advent of penicillin it is likely that more patients with acute pancreatitis will recover if the diagnosis is made early. But, in the presence of acute hemorrhagic pancreatitis or pancreatic necrosis, it strikes me that only a careful combination of medical and surgical treatment will cut down the mortality rate. I feel reasonably certain that the hospital staff that is pancreatic disease conscious will produce the best end-results.

In the following tabulation have been included the clinical entities in which blood amylase activity has been found to be increased or decreased.

Increased

Decreased

By and large a careful analysis of any given case will lead one to a correct diagnosis if one keeps pancreatitis in mind. Just the mere fact of thinking about pancreatitis is almost in itself sufficient. The laboratory aids are helpful, indeed, but one should not readily discard his years of clinical experience when a laboratory aid fails to corroborate a clinical impression.

GENERAL COMMENTS

At the beginning of this article it was stated that blood amylase activity determinations have been used with increasing success at our hospital for over 4 years. The cuprous oxide precipitation test itself is truly reliable but its successful evaluation varied at first for one or more of the following reasons:

1 Difficulty was encountered in making the medical staff pancreatic disease conscious. Now however after 4 years the test is being ordered with fair regularity in cases characterized by upper abdominal distress. The greatest comfort is derived when the report is normal or decreased blood amylase activity.

2 Difficulty was encountered in getting the medical staff to realize that while an increased blood amylase activity nearly always

implied pathologic involvement of the pancreas it did not always imply that the principal pathology lay within the pancreas. Thus a marked increase in blood amylase activity has been reported in the pneumonias (12, 14, 15), in duodenal ulcer (6, 18), in acute trauma of the spleen (11) and in mesenteric vein and portal vein thrombosis reported herein. A careful evaluation of the history and physical findings in each case will almost always lead one to a correct diagnosis.

3 Difficulty was encountered in gaining the confidence of the staff in a gross evaluation of blood amylase activity in terms of normal, increased, decreased, or by plus and minus signs. In another article (14) I have gone at length into my reasons for adopting a gross measure of amylase activity. Suffice it to state that after having performed this test more than 500 times, I am more than ever convinced that measurement of blood amylase activity by means of cuprous oxide precipitation is a quick, simple and reliable method. Anyone may perform the test. It does not take highly trained technicians and it requires only the simplest of apparatus.

SUMMARY

1 Moderate to marked blood amylase activity is almost always associated with disease of the pancreas.

2 Normal or decreased blood amylase activity almost always excludes pancreatitis. Where pancreatitis exists in conjunction with a normal or decreased blood amylase activity it may be safely assumed if the clinical status of the patient bears it out that the pancreatitis has subsided or is subsiding.

3 A slightly increased blood amylase activity may be safely regarded as indicating pancreatic involvement secondary to principal pathology elsewhere. When in doubt, tests should be repeated every day or every other day if the condition of the patient permits.

4 The presence of multiple pathology is the rule rather than the exception in acute pancreatitis. Biliary tract disease is the commonest complicating factor in this respect. An attack of acute pancreatitis may be the first clinical sign of the presence of biliary

AMINO ACIDS IN THERAPY OF DISEASE

Parenteral and Oral Administrations Compared

S C MADDEN M.D. S H. BASSETT M.D. J H REMINGTON M.D.
F J C MARTIN M.D., R. R WOODS M.D. and F W SHULL, M.D.
Rochester New York

AMINO acids were tested for their value in the treatment of human disease in the observations presented in this paper. Certain mixtures of those amino acids reported essential for the growth of rats (25) together with the amino acid glycine were given over long periods of time either parenterally or orally. *Parenterally* they were of considerable value (Tables I and III) providing nitrogen balance weight gain and clinical improvement. Similar benefit has been previously shown in man (4) and in dogs (17-20). *Orally* they maintained nitrogen balance (Table II) but in the patient studied they were not quite so well utilized as were natural food proteins.

Nitrogen balance with 8 amino acids has been obtained in normal human beings (26). These 8 are threonine valine leucine isoleucine lysine tryptophane phenylalanine and methionine. The mixtures used in the observations of this paper contain in addition to these 8 amino acids histidine arginine and glycine. It appears in Table I that histidine may be required for nitrogen balance in a patient with chronic ulcerative colitis. In normal man histidine has been omitted and nitrogen balance maintained (26-2).

Parenteral nitrogen feeding in man was first successfully reported only 6 years ago (12). Parenteral feeding is indicated and important in treatment when feeding by the gastrointestinal route is impossible or inadvisable. A very high protein intake with its beneficial results such as obtained by natural diet in the patient of Table IV would be very difficult of achievement by wholly parenteral means. Nor should it be attempted until real efforts to improve the oral intake have failed.

Complete and successful parenteral administration of protein nitrogen, fat, carbohydrate and accessories has been achieved in man (8). The studies here involving parenteral feeding were not intended to provide complete nutrition parenterally. It was desired to test amino acid mixtures given parenterally while optimum quantities of nonprotein dietary constituents were given orally. In most of the observations given in Tables I to III there was some protein present in the diet but in 2 periods presented in Table III the intake was almost exclusively from amino acids.

GENERAL MATERIALS AND METHODS

All metabolism studies were made with the patient in the metabolism division except for the study presented in Table II. Food and fluid net intakes were carefully weighed or measured and their nitrogen contents calculated from standard reference tables. The nitrogen content of some of the diets as noted in the clinical histories was checked by Kjeldahl analysis of a complete day's intake. All urine feces and vomitus were saved for analysis. Stool collection periods were marked by tomato seeds given on the first day of the period. Total nitrogen was done by macro Kjeldahl procedure and urea plus ammonia nitrogen by the method of Van Slyke and Kugel. The patients were weighed under uniform conditions on a special balance and weights at ends of periods noted (see tables).

The amino acid mixtures were somewhat similar to those used in the first patient (4). Mixture designated vuj contained in grams per 100 gram dl threonine 10.8 dl valine 13.8 1(-) leucine 15.4 dl isoleucine 10.8 1(+)-lysine. HCl H₂O 12.3 dl tryptophane 1.8 dl-phenylalanine 6.9 dl-methionine 6.2 1(+)-histidine HCl H₂O 4 1(+)-arginine HCl 8

glycine 10 nitrogen content 13.6 per cent by calculation 13.3 per cent by Kjeldahl. Mixture vu is vuj with the 1(-)-leucine replaced by the same amount of dl leucine. Mixture vu consists of dl threonine 7 dl valine 11 dl leucine 18 dl isoleucine 12 1(+)-lysine. HCl H₂O 12 1(-)-tryptophane 4, dl-phenylalanine 12 dl-methionine 6 1(+)-histidine HCl H₂O 4 1(+)-arginine. HCl 7 glycine 7 nitrogen by calculation 13.1 per cent. Mixture vus is vu with the dl-leucine replaced by 1(-)-leucine 9 gm. Mixture vub is vus with the phenylalanine reduced to 8 grams.

The amino acids were dissolved in distilled water just below the boiling point, filtered, and autoclaved for 15 minutes at 15 pounds pressure. The solutions were water clear often faintly yellowish after autoclaving. They were acid, about pH 5 except as noted.

The amino acids were given intravenously or subcutaneously in 6 to 13 per cent concentration. The concentration and volume of each injection was measured and any small quantities not given because of incomplete drainage of tube or flask were deducted. The vuj, vus, and vub mixtures were usually given in 10 per cent concentration. Mixtures vuk and vu were given usually in 7 per cent solution. The solubility of the different mixtures has largely determined the concentration employed.

ANALYSIS OF DATA

The observations recorded in Table I represent an almost perfect metabolism study of 100 days duration. The patient was intelligent and co-operative, and except for the loss of the fecal output of period 15 the measurements of nitrogen intake and output were complete.

Nitrogen balance and considerable weight gain were obtained during 85 days (periods 2 to 18) when amino acids furnished the bulk of the nitrogen intake—85 to 93 per cent except for periods 3 and 4 of about 80 per cent. Synthetic mixtures of the 10 amino acids essential for the growth of rats (25) and glycine provided this nitrogen, except for period 3 when the protein hydrolysate amigen was given. These amino acid mixtures included unnatural isomers of threonine, valine, isoleucine, tryptophane, phenylalanine and methionine, and in mixture vuk leucine. No toxicity to these unnatural isomers was detected. The amino acid mixtures of period 2 produced clinical disturbances, and nitrogen balance was not obtained (Case 1 first study Table I). Amigen in period 3, however, was well utilized and well tolerated at injection rates below 1.2 milligrams nitrogen per kilogram per minute. In period 4 the mixture vuj was similarly utilized and tolerated. It should be noted that the urinary nitrogen partition is the same with this mixture containing unnatural isomers as with amigen. With either material the undetermined fraction is higher than with oral feeding of natural protein (compare with period 1). A similar difference between intravenous and oral administration of digests to dogs has been found (19).

The oral feeding periods 12 to 14 are of much interest. Nitrogen retention was considerably greater than in the injection periods. This retention was associated with a reduction in the urea and ammonia nitrogen of the urine. In contrast to the observations in dogs (19) there was no decline in the undetermined urinary nitrogen. A rise in fecal nitrogen in periods 12 and 13 tapered off in period 14. An increase in the number of bowel movements also occurred and as detailed in the case report, the number did not return to the previous level until period 17.

Tolerance was good but not strikingly greater for mixture vuj than for amigen in this patient. Better tolerance for other mixtures of amino acids was found in the observations of Table III and in the earlier report in man (4). Better tolerance for other mixtures has also been found in dogs (21, 18). In period 10 two of the intravenous injections were made in 13 per cent concentration, both without reaction or vein injury. The nitrogen rates, however, were only 7.8 milligram per kilogram per minute.

The improved tolerance of the mixture without phenylalanine is quite definite in this patient, as described in Case 1 Table I periods 6 and 7. Omission of histidine, arginine, lysine, or methionine was without noticeable effect on tolerance. Subcutaneous injection of the amino acid mixture in 10 per

cent concentration during periods 5, 6 and 11 produced no disturbance and utilization was equal to that following intravenous injection (compare periods 10 and 11). It should be noted that this patient was an ambulatory sensitive individual to whom these hypodermoclyses were no more uncomfortable than if physiological saline solution were being injected.

Improvement in clinical condition was evident by period 3 and continued throughout the study. The underlying disease was by no means cured but its signs and symptoms were greatly alleviated. The number of bowel movements declined from 5 to 6 daily to 3 daily after only 5 days of parenteral nitrogen feeding. They were reduced to only 1 daily after period 6. Marked reduction of fecal nitrogen output was of equal interest (compare

periods 1 and 6). Symptoms of abdominal distention also disappeared. Similar clinical improvement has been observed in another patient with chronic ulcerative colitis when given amigen intravenously and a high carbohydrate low protein diet orally. Some of the clinical improvement in these cases may be due to the mental comfort of 'special treatment,' but probably not all of it.

Omission of histidine was associated during the second 5 days (period 17) with a rise in urinary nitrogen. Nitrogen balance was negative but it should be noted that nitrogen intake was less by the amount of the histidine nitrogen. We believe however that the rise in urinary nitrogen during histidine omission and its prompt return to the previous level upon histidine replacement indicates a requirement for histidine by this patient.

Weight increased steadily particularly after period 7 and even during histidine omission. Nitrogen retention over the entire period of amino acid administration does not total enough to account for the large gain. Deposit of fat probably explains most of the increase. Weight increase continued without interruption when a natural diet was given during periods 19 and 20 now with large deposits of nitrogen, and the reduction in undetermined urinary nitrogen was striking.

CASE 1: First study M. E. (SMH 203 158) was a 26 year old white painter with ulcerative colitis of 6 months duration when the observations presented in Table I began. Two months previously he had left the hospital after a stay of 6 weeks. During this first admission no cause could be found for the colitis. Upon fluoroscopy the colon appeared large and its wall smooth. Upon sigmoidoscopy it showed many fine bleeding points but no distinct ulceration. Stools were 7 to 8 daily a reddish liquid, half red blood cells and half leucocytes upon microscopic examination, but during bed rest, high protein and vitamin intakes, blood transfusions, and sulfasuccidine therapy the number of bowel movements decreased to 3 to 4 per day. Out of the hospital some of this improvement was lost and the weight had declined from 58 to 53 kilograms. Upon the present (second) hospital admission it was suggested that a very low residue diet might be advantageous. After 6 days of routine care in the hospital the patient was transferred to the metabolism division. He remained ambulatory on the division throughout his stay.

In period 1 a soft "low residue" diet of natural foods was consumed. It provided daily protein 127 grams and calories 3104. The same diet was eaten during the last 2 periods (19 and 20) but during the intervening 17 periods a very low protein diet was given. The low protein diet varied somewhat until the eighth period and thereafter remained fairly constant. For the 10 periods (9 to 18) it consisted in grams, of orange juice 400, grapefruit juice 200, lemon juice 70, currant jelly 50, gum drops 300, sucrose 50, dextrose 235, corn starch 200, tapioca 10, cocoa 5, butter fat 40, cream (butter fat 36 per cent) 50, salt 2, baking powder 5. A corn starch-butter fat tapioca "biscuit" was baked and corn starch-cream-fruit juice puddings were frozen. This diet contained by Kjeldahl analysis 138 grams nitrogen and a calculated 3700 calories.

The actual caloric intake of the second period averaged 1977 including the amino acids and of periods 3 to 7 varied between 3,300 and 3,500 including the calories from the amino acids (calculated as nitrogen $\times 15$). A vitamin B complex concentrate was given during the first 7 periods and thereafter a multiple vitamin emulsion (10 c.c. daily) described elsewhere (16). Sulfasuccidine 12 grams, ferrous

sulfate 0.5 gram, and intramuscular liver extract (1 unit per c.c.) 2 cubic centimeters were all given daily during periods 8 to 20. On the bare possibility that insulin might encourage the appetite for the high carbohydrate diet 10 units was given 30 minutes before each meal beginning in period 8. The diet was fairly readily eaten.

During periods 2 to 18 amino acids were given as recorded in Table I. They were injected twice daily through period 8 and once thereafter.

In period 2 mixture vu6 (vub with di-tryptophane) was first given, 45 grams in 30 minutes, and the patient became nauseated. He vomited during the next injection of 87 grams. The vu mixture, used at rapid rates without reaction in the observations of Table III, was then given, 50 grams in 105 minutes (1.5 mgm. nitrogen per kilogram per minute) without nausea and in 85 minutes (1.5 mgm. nitrogen per kilogram per minute) with nausea and vomiting. Nausea twice and vomiting once occurred with 3 of the remaining 6 injections. Vomitus nitrogen 1.5 grams was deducted from the intake in Table I.

In period 3 amigen (an enzymatic digest of casein and pork pancreas) in 5 per cent solution with 5 per cent dextrose was used. A total of 10.43 liters was given in 10 injections, the injections varying from 100 to 200 minutes in length. Only the one at 100 minutes (1.5 mgm. nitrogen per kilogram per minute) produced nausea.

In period 4 mixture vu7 was given in approximately the same quantities (in 65 to 190 minutes per injection) with nausea on 2 occasions at 2.7 milligrams nitrogen per kilogram per minute. Dextrose, 5 per cent, was included in the amino acid solution during the period for more exact comparison with the amigen of period 3. During periods 4 to 6, the amino acid solution was adjusted to a pH of 6.5 by addition of sodium hydroxide—with no apparent effect on tolerance.

On each of the first 3 days of period 5 the large quantity of 105 grams vu7 mixture was given with vomiting during 3 of the 6 injections. Omission of lysine, histidine and arginine during one of these did not prevent vomiting. The amount given was reduced to half on the last 2 days omission of methionine on 1 day did not prevent vomiting. These omissions of essential amino acids were associated with a weight loss from 54.12 kilograms at the beginning of the period to 53.18 kilograms at the end. Vomitus nitrogen of 3.5 grams was deducted from the intake in Table I.

In periods 6 and 7 mixture vu7 65 grams, was injected twice daily usually once by vein and once subcutaneously. There was nausea on 2 occasions but usually no disturbance occurred when the rate was near 1 milligram nitrogen per kilogram per minute. On the last day of period 6 phenylalanine was omitted from both injections (by vein). There was no reaction to the injections given in 95 and 55 minutes, respectively, (1.5 and 2.6 mgm. nitrogen per kilogram per minute). The day's intake of phenylalanine when started 45 minutes after com-

TABLE II—AMINO ACIDS ORALLY COMPARED WITH AMIGEN AND WHOLE EGG

M. E., aged 26 years, chronic ulcerative colitis

Period in days	Diet	Nitrogen intake per period		Nitrogen output per period				Nitrogen balance per period	Weight
		Amino acids	Basal	Urine (total)	Urine urea-NH ₂	Urine non- biureted	Feces		
1	V I	Grams 85.6	Grams 5	Grams 8.3	Per cent 72	Grams 5	Grams 37.9	Grams - 8.3	Kilograms 55.6
	VaI	86.6	5	13.3	65	8.6	13.7	+ 6	50.3

4	Amigen	126	5	6.0	78	14	65	+1	50.5
6	Egg		87.9	40.6	73	11	37.6	- 1	50.0

pletion of the second injection produced nausea at a rate of 0.6 milligram nitrogen per kilogram per minute.

When the mixture was given the next day (first day of period 7) with phenylalanine included vomiting occurred at a total nitrogen rate of 1.7 milligrams per kilogram per minute phenylalanine nitrogen rate of 0.08 milligram per kilogram per minute. The next day mixture was subcutaneously at 2.9 milligrams total nitrogen per kilogram per minute was followed by vomiting 45 minutes later. When phenylalanine was again omitted on the third day of period 7 the two injections (4 hours apart) were given by vein at 4.3 and 3.1 milligrams nitrogen per kilogram per minute without nausea or vomiting. The phenylalanine given 30 minutes after the second injection produced vomiting at the nitrogen rate of 0.3 milligram per kilogram per minute when 10.8 milligrams phenylalanine nitrogen per kilogram had been injected. The next day no reaction occurred to the complete mixture at 1.1 milligrams nitrogen per kilogram per minute, but 30 minutes after subcutaneous injection of the second dose at 5.6 milligrams nitrogen per kilogram per minute vomiting occurred. The vomitus nitrogen for period 7 amounted to 2.07 grams.

In period 8 the mixture was changed to yuk at the same intake level as in periods 6 and 7. No nausea or vomiting occurred at the slow rates of 0.7 to 0.9 milligram nitrogen per kilogram per minute.

In periods 9 to 11 the amino acid intake level was reduced to half that of period 8 and injections were usually at the same slow rates even when given subcutaneously (period 11). At the end of period 9 and during part of period 10 the patient had for 3 days a sore, red pharynx and fever to 39.5 degrees C. It subsided uneventfully. Cultures were nonspecific.

In periods 12 to 14 the amino acids were given by mouth, the 10 per cent solution being mixed in the fruit juices and frozen puddings. After the first 2 days the patient stated that the taste was not unpleasant.

In period 15 the stool collection was accidentally discarded. Periods 16 to 20 were uneventful.

The patient's symptoms of abdominal discomfort subsided entirely during the early periods. The number of bowel movements decreased sharply during periods 1 to 7 the numbers per period being 27, 30, 17, 13, 10, 13, and 4, respectively. There was one stool a day during periods 8 to 11 but when the amino acids were given orally in periods 12 to 14 the numbers per period were 10, 9, and 8 respectively. During periods 15 to 18 the number declined again 9, 7, 5, 6 and in periods 19 and 20 on the same diet as period 1 were 3 only during each period. The stools did not become formed until the last two periods, and, although no blood or mucus was visible still did not appear normal.

During the first 7 periods the plasma protein level rose from the region of 5.7 to the region of 6.3 grams per 100 cubic centimeters of plasma and remained there during the remaining periods except for dips to 5.8 during periods 10 and 11. The albumin/globulin ratio remained about 1.7 most of the time. The serum nonprotein nitrogen, chlorides, and plasma carbon dioxide combining power varied within normal ranges. The hemoglobin rose from 11.1 to 13.2 grams while the red cell count remained at 4,200,000.

At the end of the study fluoroscopy showed improvement of the colon as compared with its appearance at the beginning of the study. Sigmoidoscopy however still showed bleeding points and excessive secretion in a reddened edematous mucosa. No ulcers were seen. The patient was discharged to work as a hospital orderly to be kept under observation. Subjectively and objectively he was temporarily greatly improved (Case 1, Table II).

In Table II the effects on nitrogen metabolism of giving amino acids and amigen by mouth are shown. The salutary effect on the symptoms of colitis in the observations of Table I suggested that an attempt to relieve these symptoms which had recurred should be made by oral administration of the amino acids. The symptoms were not relieved (Case

1 second study Table II) but the observations are of interest.

The amino acids appear in this instance to be better tolerated by the intestine than amigen but amigen appears better utilized upon absorption from the intestine. These factors combine to yield approximately the same net retention of nitrogen in periods 2 to 5. The negative balance of period 1 probably reflects the change from the higher level of nitrogen intake which probably preceded the relatively low level of period 1.

The egg nitrogen of period 6 Table II is better utilized than either the amigen or the amino acids, as judged by the relation of intake to urinary output, but the loss through the intestine offsets this advantage.

The weight remained fairly constant through out the observations (Table II). The gain registered in Table I on similar intakes did not occur here probably partly because of increased caloric demand during activity out side of the hospital.

CASE 1: Second study M. E. (SMH 203 158) was the same patient studied in the observations recorded in Table I. He worked for 1 week upon discharge from the hospital, then his old symptoms began to return gradually. Within 3 weeks he was having 8 to 9 bowel movements a day and soon had an acute febrile exacerbation. This gradually subsided during hospitalization and vigorous supportive therapy. During the first 2 months of this relapse his weight had declined to 47.6 kilograms but rose to 52 kilograms upon discharge from the hospital 3 weeks later. During the next 2 months he gained weight despite continuance of frequent loose stools.

As a co-operative out-patient he was eager to test the influence of the low residue diet again with amino acids by mouth, so that the conduct of the experiment was entirely satisfactory. The amino acids were weighed in the laboratory and the basal diet was weighed on a special balance at home. The basal diet for the entire 6 periods was identical with that of periods 9 to 18 (Table I) except for omission of the cream and the cocoa. It had a daily nitrogen content of 0.5 gram. The vitamin emulsion used was the same as that in the observations recorded in Table I. Urine was collected in 2 day periods under toluene with refrigeration, and analyzed the following day. Stools were collected in 10 day periods. The weight at the beginning of period 1 was 58.6 kilograms.

In periods 1 to 3 the amino acid mixture and the diet were completely consumed. Vomitus nitrogen the first day of period 1 was deducted from the intake. The acids without methionine were fairly innocuous to the palate, so that the patient took the

methionine separately "as medicine," in divided doses to accompany the three meals a day.

In periods 4 and 5 amigen powder was dissolved and suspended in the diet, 75 grams daily in period 4, 100 grams in period 5 with 150 grams on the first day. It was tolerated although less palatable than the crystalline amino acids. An exacerbation of symptoms with abdominal pain and increased tenesmus and bleeding occurred during the last 2 days of period 4 and the first of period 5. Sulfanacide was then given for 6 days, and although the diarrhea increased for 4 days the other symptoms subsided.

The symptoms of colitis continued without relief during the 60 days of these observations. In fact the number of bowel movements rose from 8 to 10 daily prior to period 1 to 11 to 14 daily during period 1 totalling 120. During periods 2 to 6 the totals were 98, 111, 114, 145 and 124 respectively. The stools contained much mucus, and frequently blood.

In period 6 the protein intake came from 1 pound of hens' eggs daily (12 ounces on the first day). The nitrogen of the total diet of 1 day was determined by Kjeldahl analysis. On the fourth day of the period the patient had a transient upset and vomited once, nitrogen content 1.18 grams. He had lost his appetite for this stringent regimen by the close of the period and returned to his soft, more varied diet.

Table III further demonstrates the value in preoperative and postoperative care of parenteral feeding with amino acids. The patient J.S. with chronic intestinal obstruction was maintained in positive nitrogen balance by intravenous and subcutaneous injection of amino acids, despite an intercurrent acute infection during periods 1 and 2. Moreover during period 1 the nitrogen intake was entirely from amino acids except for 0.6 gram on 1 day only.

When no amino acids were given during period 4 the patient was unable to maintain adequate nutrition by mouth. Operation on the last day of this period corrected the obstruction (Cases 2 and 3 Table III).

Postoperatively J.S. (period 5) had an uneventful course and recovered rapidly. Nitrogen balance was maintained despite the serious injury of a major operation. The day-by-day balances of period 5 if one assumes equal division of fecal nitrogen, were +3.0, 0.4, 1.9, +2.4, and +2.7 grams, respectively. This is not the usual postoperative course of the nitrogen balance (10, 7, 15) but allowance must be made for the fact that the patient was emaciated. With zero intake of nitrogen the balance will obviously be negative in any case.

*Grosses of vomitus and Wangenstein drainage deducted

If the nutrition is relatively normal preoperatively the balance will be markedly negative postoperatively. If the patient is protein depleted before operation the negative balance is much less (6). With moderate caloric and protein (or amino acid equivalent) intake balance can be maintained in such depleted individuals, as demonstrated in the present instance. Previously normal individuals require larger intakes of nitrogen, or possibly special kinds of nitrogen (18-9).

Patient H.S. Table III presented the difficult problem of nutrition in a jaundiced patient after a major operation. Anorexia and vomiting were severe and the superficial veins were very difficult to use for injection purposes. All but 2 of the 20 injections during the 10 days of study were made subcutaneously. Tolerance was good to the 10 per cent amino acids subcutaneously and on 2 occasions injections of more than 12 per cent concentration were given in period 1 without the slightest upset.

Nitrogen balance was approximated in the 2nd period with patient H.S. Table III when the entire nitrogen intake was being provided by amino acids. The undetermined urinary nitrogen fraction was proportionately lower with mixtures vu_a and vu_b (as well as with vu_j Table I) than with vu. This may be in direct evidence of poor utilization of the

unnatural d(+)-leucine contained in the vu mixture. Some conversion of d(+)-leucine into the l(-) form occurs in rats (23).

CASE 2. J.S. (SMH 199516) was a 21 year old, white college student with recurrent episodes of abdominal pain and vomiting during the past 7 years. He was emaciated and pale, weight 35.5 kilograms, height 175 centimeters. He had never shaved but his sexual development appeared normal. Fluoroscopy following barium showed several dilations of ileum which were followed by an apparent obstruction.

To attempt to improve the condition of the patient before operation he was transferred to the metabolism division 4 days prior to period 1. Table III for special diet control. Further oral feeding was tried the first 3 days on the metabolism division but vomiting of large amounts of fluid and food occurred every evening. The weight was raised to 37.4 kilograms 2 days before period 1 began largely by retention of saline infusions. A Miller Abbott tube was passed into the jejunum the day before period 1 and distention was relieved but vomiting of ingested food and fluid persisted. An aphthous stomatitis, pharyngitis, and esophagitis began the day before the tube was passed and continued during periods 1 and 2.

In period 1 the amino acid mixture vu_a 200 grams was given daily and the caloric and vitamin intakes were provided by a fortified lemonade and synthetic vitamins and concentrates. There was no clinical disturbance which could be attributed to the amino acids. Fever between 38 and 39.5 degrees C accompanied the stomatitis and near the end of the period an area of patchy density by x ray was found in the right lower lobe. Sulfadiazine was given with questionable benefit.

The average daily caloric intake was 1,800. Other pertinent laboratory data were plasma protein 4.0 grams per 100 cubic centimeters plasma, nonprotein nitrogen 23 milligrams per 100 cubic centimeters serum chlorides 107 milliequivalents per 100 cubic centimeters serum, carbon dioxide combining power 41 volumes per 100 cubic centimeters plasma, hemoglobin 9.5 grams per 100 cubic centimeters blood, leucocyte count 8,600 per cubic millimeter blood. The nitrogen in the vomitus and Wangenstein drainage amounted to 2.6 grams.

In period 2 the amino acid solution was modified on one day by addition of sodium carbonate of sodium content chemically equivalent to the chloride content of the amino acids. The resulting solution had a reaction of pH 8.45 and after subcutaneous injection of 100 grams amino acids in 1600 cubic centimeter solution the patient's thighs were sore and reddened and a small blister appeared at the site of the needle puncture. This irritation subsided without further progression. All other injections at the usual acid pH 5 produced no disturbance. The daily food and amino acid intake averaged 1,605 calories. The small amount of protein came from a processed vegetable soup butter and cream, and tapioca. The remaining diet consisted of fruit juices, sucrose, lactose and corn starch. There was no vomiting. Laboratory data did not change significantly.

Throughout period 3 the amino acids were given intravenously without reaction. The plasma nitrogen given, totalling 5.83 grams, and the red cell nitrogen, 19.35 grams, are not included in the nitrogen intake of period 3 Table III. The patient's general condition showed much improvement by this period. The caloric intake averaged 3,623 but on the last day he vomited a large amount of fluid and food nitrogen content 1.17 grams. Before the first transfusion the total protein of the plasma was 3.8 grams per 100 cubic centimeters after the second transfusion it was 4.8 grams per 100 cubic centimeter. There was no edema at any time. The albumin globulin ratio was 1:5.

In period 4 the patient was tested again on voluntary feeding. He complained of fullness after moderate intakes on the first 2 days and vomited on the third day 128 grams nitrogen including gastric washings from a Levine tube which was then inserted. Food intake was very poor on the third and fourth days and not accurately known. On the fifth day his abdomen was opened under general anesthesia and chronic intestinal obstruction was found due to chronic inflammation of lower jejunum and upper ileum beginning about 2 feet distal to the ligament of Treitz. A segment of ileum about 12 inches long was resected and a side-to-side anastomosis done. The specimen showed 3 greatly narrowed thick walled areas with intervening dilatations as much as 7.5 centimeters in diameter. The mucosa was ulcerated and microscopically there was a non-specific acute and chronic inflammation. The picture was not thought to be entirely like that of regional

enteritis. The patient withstood the operation well. A liter of normal saline was given under the skin. Sulfathiazole was placed in the wound and sodium sulfadiazine was given intravenously for 3 days postoperatively. The day before operation the plasma protein level was 3.5 grams per 100 cubic centimeters. The stool collection for this period was accidentally discarded without nitrogen analysis.

In period 5 amino acids 200 grams daily were given for the first 3 days and 100 grams thereafter. Sodium lactate chemically equivalent to the chloride content was given with the amino acids. The patient had an afebrile postoperative period except for a rise to 37.9 degrees C. on the day after operation. He took clear fluids moderately well for the first 3 days postoperatively and then increased to a diet similar to the preoperative one. The caloric intake averaged 1,542 calories daily being 2,550 on the last day. On this fifth day he complained of feeling queer midway during the first injection of amino acids (50 gm. in 150 minutes) and again about 2 minutes after the second injection (50 gm. in 6 minutes). He could not describe the feeling except that there seemed to be a sense of fullness of the abdomen. The plasma protein concentration rose from 4.5 at the end of the second postoperative day to 5.4 grams per 100 cubic centimeter at the end of the fifth day after operation.

In the sixth period the amino acids were discontinued and diet was changed to include steak, milk eggs, and other foods totalling 18.8 grams nitrogen and 3,310 calories per day but was less than two thirds consumed the first 3 days. General condition and appetite continued to improve. Total plasma proteins at the close of the period were 5.9 grams per 100 cubic centimeters.

The metabolic study was continued for 8 periods beyond those of Table III with the same diet intake with and without testosterone and has been reported elsewhere (3). Nitrogen retention was great and at the end of the 40 days the weight was 49 kilograms.

CASE 3. H.S. (SMH 203 122) was a white female aged 53 years, with obstructive jaundice. At operation the gall bladder and common duct were distended with stones and white bile and a hard nodule was palpated in the head of the pancreas. After cholecystogastrostomy the icterus subsided very slowly the wound drainage was bile stained and the patient's general condition and food intake were very poor. Thirty days later another exploration revealed that the common duct wound had broken down and the cholecystogastrostomy had closed. Cholecystojejunostomy was performed with the patient in and out of shock. Food and fluid intake after operation were very poor for 3 days. There was much vomiting. The patient's veins were poor for intravenous work. On the third postoperative day amino acid feeding was begun. At this time the plasma protein concentration was 4.8 grams per 100 cubic centimeters, plasma albumin 3.0 grams per 100 cubic centimeters, serum chlorides 100 mill

TABLE IV—HIGH PROTEIN FEEDING INFLUENCES RAPID HEALING OF CHRONIC WOUND

O. M., aged 8 years, unhealed burn, duration 1 year

Period (days)	Clinical remarks	Nitrogen intake per period	Nitrogen output per period				Nitrogen balance* per period	Weight
			Urine Total	Urine urea-NH ₃	Urine acid- termed	Feces		
1	Black grafts	Grams 84	Grams 55.6	Per cent 87	Grams 7.0	Grams 4	Grams +24	Kilograms 0
	Two grafts	04	50	86	8.3		+15	
3	Black grafts	80	51.6*	87	6.8	9	+3

8		07	67*	83	8	10.7	+24	

*Calculations—balance estimated.

equivalents per 100 cubic centimeters icterus index 35.

In period 1 amino acids were given subcutaneously twice daily except for 3 intravenous injections. The alone intake was poor as the patient tended to vomit when anything accumulated in the stomach, and the net intake may be estimated at not over 500 calories per day including amino acids. No nausea or vomiting or other reaction was observed in relation to the amino acid injections. The entire food intake consisted of orange juice and lemonade fortified with sugar and on 1 occasion a little tomato juice. The vomitus nitrogen amounted to 1.15 grams. Three plasma and 1 whole blood transfusions were given and their nitrogen content (about 25 gm.) is not included in the intake of period 1. The patient had considerably improved in clinical condition and subjective appraisal of life by the end of the period. The plasma protein total was now (last day of period) 6.4 grams per 100 cubic centimeters and the plasma albumin 3.3 grams, the icterus index 16 and the serum chlorides 103 milliequivalents per 100 cubic centimeters.

In period 2 amino acids were given entirely subcutaneously and the patient, now more alert and co-operative, retained daily an estimated total of 1600 calories, after deducting for loss in vomitus. Vomitus nitrogen amounted to 1.51 grams. The effect of the plasma transfusions was not sustained and the level of plasma protein declined 24 hours later to 5.0 grams per 100 cubic centimeters (first day of period 3).

A liquid diet was given after period 3 and the patient slowly but steadily improved and left the hospital. She returned 10 months after the observation of Table III and died in the hospital. At autopsy carcinoma of head of pancreas was found.

The study in Table IV is presented in this report because of the importance of the thera-

peutic principles it emphasizes. Chiefly these are that a high protein intake may shorten illness and save lives, and second that the best source of a high protein intake is a diet of natural foods—useful and spectacular though parenteral feeding may be.

The patient in this case had been treated in two hospitals for an entire 12 months (See Case 4 Table IV). She had been treated competently in all respects except for control of diet. Good diets had probably been ordered but no measurement of actual intake had been made. The plasma protein level was not regarded as low but it was suggested by those in charge of the case after 1 month in the second hospital that parenteral feeding with amino acids might build up the patient enough for grafts to take and grow.

There was no barrier in the patient to normal eating except lack of appetite for the routine diet. Therefore oral feeding not parenteral was indicated. The diet prescribed on the metabolism division catered to the child's taste and the intake was measured.

Within 2 months from the beginning of Table IV virtually complete healing was accomplished of what had resisted all previous treatment during 10 months. We do not mean to imply that the very high level of protein feeding used in this case (5 to 6 gm protein per kilo) was absolutely essential to its success. A somewhat lower intake might have succeeded though probably less rapidly.

Voluntary uncontrolled intake was not sufficient.

Attention should be directed to the *plasma protein level*. The total plasma protein was nearly 6 grams per 100 cubic centimeters at the beginning of Table IV. Yet the body was unable to mobilize enough protein to produce tissue to anchor skin grafts. Evidently the body was thoroughly depleted of protein even though the circulating plasma protein level was at the lower edge of the normal range. After high protein feeding with much protein being produced and retained the circulating plasma protein level was 7 grams per 100 cubic centimeters or higher. Such an observation suggests that a plasma protein level of 6 grams per 100 cubic centimeters may correlate with a poorer state of health than higher levels within the normal range.

The nitrogen balance data in Table IV are only approximately accurate in that intake was calculated from standard diet tables rather than actual chemical determination and output was not always completely measured on account of incontinence. In addition nitrogen loss from the wound surface was not continuously measured. There can be no doubt, however, that the balance was strongly positive in all periods except the 6th and the rapid clinical improvement and weight gain eloquently confirm the value of the treatment.

CASE 4. O.M. (SMH 213 143) was a thin white girl of 8 years with an unhealed burn of her right thigh and leg. One year and 11 days before the beginning of the observations of Table IV she sustained a burn, largely 3rd degree, from a fire started in bed by a faulty electric heating pad. Four days later she was taken to an adjacent hospital. Infection was treated with sulfonamides.

Three months after the burn pinch grafts were applied unsuccessfully. They were tried again a month later still unsuccessfully. Eight months after the burn the granulating area was considered safe again but the patient went into shock under the anesthesia before the grafts could be taken and applied. Plasma applications were made locally and more sulfonamide therapy was given locally. Ten months after the burn the patient was transferred to this hospital.

On admission she was thin and pale and 70 per cent of the surface of her right lower extremity was a pink wet granulation tissue devoid of skin. There was a 15 degree contracture at the knee. The plasma proteins were 6.36 grams per 100 cubic centimeter by refractometer and the other routine laboratory

tests appeared normal. A high protein high vitamin diet was ordered and as much assistance was given her with eating as could be spared on a busy pediatric division. She ate fairly well.

During the first month she had an upper respiratory infection and some intermittent fever possibly related to wound infection. Measurement of the nitrogen loss from the granulating surface was done by determining the nitrogen content of the dressings with correction by deducting the small nitrogen content of equivalent unused dressings. The measured loss was 1.06 grams nitrogen per day. Five weeks after admission, large split thickness skin grafts were applied with thrombin technique by Dr. Forrest Young. They did not take.

The reason for the failure of the grafts was not apparent. Infection was controlled. The plasma protein level was above 6 grams per 100 cubic centimeters and although thin the patient was eating and did not appear emaciated. It was, however, considered desirable to improve the nutritional status and a request for amino acid injections was made. The patient was transferred to the metabolism division. Since the patient was co-operative and could eat normally it was decided to urge the complete consumption of a measured high protein diet. Foods were selected according to the tastes of the patient. The diet was accurately weighed and net consumption carefully measured. Vitamin supplements were continued exactly as during the preceding 3 months. These were ascorbic acid 50 milligrams, brewer's yeast tablets 15 grams and oleum percomorph 1.0 milliliter daily.

At the beginning of period 1 the patient weighed 19.18 kilograms including wet dressings. The plasma protein level was 5.90 grams per 100 cubic centimeters (by macro-bioklinal analysis) the plasma albumin 3.70 grams per 100 cubic centimeters. The plasma chlorides and carbon dioxide combining power were normal. There was no evidence of dehydration. Seven days before the beginning of period 1 about 12 pinch grafts were applied.

The diet contained in grams: milk 800, whole egg 100, lean ham 100, frankfurter 100, lean ground beef 100, bacon 30, American cheese 50, frozen fresh peas 50, dried prunes 50, white bread 50, butter 30, sugar 30, cocoa 15. The diet is calculated to contain about 132 grams protein and 2360 calories, with roughly equal weights of protein, carbohydrate, and fat. For a patient of 19 kilograms it provides 6.9 grams protein and 124 calories per kilogram, as much as required by a newborn infant. The diet was not given in its entirety as listed, during any complete 5 day period. The patient ate very well, and usually most of the day. Some modifications were made and on some days portions of the diet were not eaten. All of these were weighed back and deducted from the net intake. The net intake for example, of period 1 was above 6 grams protein per kilogram. Urinary nitrogen outputs were determined in 24 hour periods, fecal nitrogen in 5 day periods.

In period 2 it was strikingly evident that the recent pinch grafts were taking. In addition spreading of new epithelium could be seen about some old grafts which had previously been buried by granulation tissue. The food intake continued high despite the occurrence of acute tonsillitis with fever.

More pinch grafts were applied in period 3 and as these grew and the patient's weight and strength improved markedly in periods 4 and 5 it was decided to cover the whole area again with split thickness grafts. This was done at the beginning of period 6. The patient stood the procedure well but there was no food eaten the first day and reduced quantities for the rest of the period.

All the grafts took and healing proceeded well. The high diet intake was continued for 20 days beyond period 8. Table IV but accurate measurements were not made. The entire lower extremity was covered by intact skin at this time except for one small bare area which healed during the next 4 weeks. The patient now weighed 24.3 kilograms.

During periods 3 to 8 the patient had occasional nocturnal convulsions. The amounts of nitrogen lost were estimated by reference to the output on adjacent days when complete collection was obtained and the balances given in Table IV were corrected by these amounts. Slight vomiting of food occurred after the large feedings in periods 6 and 7 and this was deducted from the intake—2.1 grams nitrogen in period 6 and 2.3 grams in period 7. The plasma protein level rose from the initial 5.9 grams per 100 cubic centimeters to 7.10 grams by the end of period 4 and remained at this normal level. The plasma albumin level rose from 3.70 to 4.40 grams per 100 cubic centimeters.

After a month of physiotherapy the patient walked out of the hospital. She had slight residual contracture of the knee. There was some foot drop possibly due to burn injury to the superficial peroneal nerve.

EVALUATION

Of what are amino acids capable? When is their use indicated? Are they toxic? Are they practical? Answers to all these questions are not completely given in the comments accompanying the observations presented but the trends of the answers are suggested.

Proper mixtures of amino acids are capable of providing the protein nitrogen requirements of man and animals over long periods of time. They may be given either by mouth, by vein or by subcutaneous injection. Intraperitoneal injection has been successfully used in the dog (20). The importance of continuously adequate nutrition need not be discussed here. Either mixtures of crystalline amino acids or certain protein digests are capable of providing the protein share of it.

The formula for the perfect preparation of protein nitrogen is yet to be written. There are advantages and disadvantages to all substitutes for natural protein. Digests are of less known composition, more difficult of reduplication, more inflexible in composition, currently are less tolerable upon rapid injection than certain synthetic mixtures of amino acids. On the other hand they are inexpensive to produce. Amino acid mixtures contain the unnatural isomers of certain amino acids, but as discussed later no real toxicity has been demonstrated for these unnatural isomers. The question of better utilization of amino acid mixtures or digests favors the former as judged by plasma protein production experiments in dogs (20). There appears to be little difference between amigen and mixture vuj intravenously in the brief test in Table I. By mouth, in the comparison of Table II, amigen is associated with a lower undetermined fraction of urinary nitrogen but this test is clouded by the exacerbation of diarrhea (Case 1, Table II). Use of the mixture vuj in dogs (18) indicates a lower tolerance for it than the tolerance for some other mixtures (21). These latter and others should be tested in man.

Uses for amino acids other than the general nutritive one may be expected to appear. Individual amino acids or mixtures of individuals may be involved. The use of methionine in circumventing or alleviating toxic agents has been described in dogs (22, 23) and tested clinically (5, 14). It is a further stimulating suggestion that most of the effect of added protein intake in preventing negative nitrogen balance after injury (18) may be achieved equally well by added methionine (9), an observation not yet confirmed (27).

Indications for the use of amino acids for nutritional purposes exist only when natural protein cannot be effectively used. The study in Table IV demonstrates the importance of vigorous effort in the use of natural protein. Anyone who might order parenteral feeding in such a case because of its superficial ease or therapeutic impressiveness can recognize from such comparisons in Tables I and II that efficiency of utilization may be sacrificed somewhat. However for the feeding of pa-

tients who cannot or should not be given protein by mouth their value parenterally is great.

There are indications for their use orally. They appear to have marked value in the treatment of peptic ulcer from the interesting work of Co Tui, using amigen. Here their buffering capacity may be as important as their nutritive value. Used to fortify the diets of protein depleted individuals they should theoretically have considerable value. Such individuals must have reduced capacity to secrete the intestinal enzymes, which are proteins. Predigested protein should therefore be better handled. To illustrate this point an observation of Reisenstein and Al bright is pertinent. A young man fed wholly by parenteral amigen and glucose for 26 days was given at the next meal a full diet of natural food by mouth. He accepted it and digested it without the slightest disturbance. A fasting individual protein depleted would usually not be capable of this but must start with cautious feeding gradually increased. The difference appears to lie in the reduced capacity of the depleted individual to produce gastrointestinal juices and enzymes.

A serious toxicity has yet been described with the use of proper amino acid mixtures or digests. Intolerance to the rapid injection of amino acid mixtures containing glutamic acid or much aspartic acid is manifested by vomiting in dogs (21, 16). The usual casein digests contain considerable glutamic acid. It is suggested in the observations of Table I of this paper that phenylalanine may be less tolerable than the other essential amino acids. Toxicity has been inferred for unnatural isomers but is not proved by the demonstration of interesting urinary metabolites related to their administration (1).

The use of amino acids will become increasingly practical. Further improvements are desirable in the palatability of oral preparations. Greater availability of the more tolerable intravenous preparations, such as proper mixtures of the crystalline amino acids or of digests free of glutamic acid and aspartic acid should be provided. Complete parenteral feeding is not now limited by the nitrogen intake so much as by the lack of suitable

means of providing a high caloric intake. Efforts to produce a satisfactory fat emulsion for intravenous administration have been long but are not yet successful (17).

SUMMARY

There are two sources of protein for meeting the needs of the body. One is that portion of body protein which can be mobilized for a particular need in time of emergency—called the reserve protein. The other is the main and ultimate source of protein—the exogenous intake, normally dietary.

Of the two general routes for supplying the exogenous protein needs in disease therapy the oral route is shown to be preferable. The parenteral routes are shown to be valuable, even life-saving when oral intake is impossible or inadvisable.

Mixtures properly prepared of the crystalline amino acids threonine, valine, leucine, isoleucine, lysine, tryptophane, phenylalanine, methionine, histidine, arginine and glycine are adequate for the protein nitrogen needs and marked weight gain of patients over long periods of time. Given parenterally as the sole protein nitrogen intake these amino acids are adequate for nitrogen balance in human patients.

Histidine omission from a mixture of amino acids given intravenously to a patient with ulcerative colitis resulted in a negative nitrogen balance.

One amino acid mixture gave similar nitrogen retention and urinary nitrogen partition to that obtained with the protein hydrolysate amigen during a brief comparison. Neither was quite so well utilized parenterally as orally and neither was quite so well utilized orally as the better natural food proteins.

No toxicity to the unnatural isomers of 7 essential amino acids was demonstrated.

These crystalline amino acid mixtures are well tolerated subcutaneously as well as intravenously even in more than 12 per cent concentration in aqueous solution. It appears, moreover, that further improvements in tolerance can be made. Phenylalanine has been shown to be a limiting factor in tolerance.

Marked clinical improvement occurred in a patient with chronic ulcerative colitis fed

certain amino acid mixtures parenterally together with carbohydrate fat, and accessories orally. No improvement occurred when the amino acids were also given orally.

The value of certain amino acid mixtures in the preoperative and postoperative nutrition of 2 patients was also demonstrated.

Plasma protein levels in the range commonly regarded as low normal may be found in patients showing virtually complete exhaustion of body protein reserves. A high protein intake actually measured and given to such a protein depleted patient with a chronically unhealed wound brought about complete healing after all other treatment had failed.

REPAIR OF LARGE ABDOMINAL DEFECTS BY PEDICLED FASCIAL FLAPS

OWEN H WANGENSTEEN M D F.A.C.S Minneapolis, Minnesota

TWO PEDICLED FASCIAL FLAPS FOR CLOSURE OF LARGE DEFECT IN UPPER ABDOMEN

LARGE fascial defects in the upper abdomen as a result of antecedent operations are difficult of satisfactory closure by any method. A number of years ago (1932 and 1934) the present writer described the repair of recurrent and difficult hernias and other large defects of the abdominal wall employing the iliotibial tract of fascia lata pedicled on the tensor fascia femoris muscle as a graft. This method constitutes a very satisfactory means of dealing with large defects of the abdominal wall situated below the umbilicus. Even in patients with long femurs, the longest possible length of iliotibial tract of fascia is usually too short for the repair of defects immediately beneath the costal margin without tension. Furthermore attempts directed at approximating the widely separated fascial edges in an incisional hernia of wide dimensions anywhere in the abdomen are probably ill advised. First because sutures tied under tension invite necrosis of the approximated tissues and the recurrence of the hernia. Second leaving the abdominal wall tight as a drum in the process of repairing a large ventral bulge may in itself invite disaster owing to the baneful effects of increased abdominal pressure.

Necessity compels search for a satisfactory method of dealing with such hernias. In the latter part of 1944 when confronted with a very large hernia in a vertical incision extending from the ensiform cartilage to a few centimeters below the umbilicus I hit upon the method to be described herein. Fortunately however the patient was thin and it was possible to approximate the wound edges of the defect without too great tension. A few months later however a patient presented

himself with a large defect originating beneath the right costal margin and extending well beyond the midline. At operation the fascial defect measured 24 centimeters in length and 18 centimeters in width. No local sliding of tissue could possibly have succeeded in closing the defect. The antecedent story is as follows.

Mr. L. L. aged 63 years, University Hospital No. 78025 was admitted with acute intestinal obstruction associated with large distention of the colon on June 31, 1943. Transverse colostomy was done a few hours after admission. The intraluminal pressure was 3 centimeters of water, 3000 cubic centimeters of gas was aspirated on closure of the skin. On June 30, 1943 primary resection was done for the obstructing carcinoma of the pelvic colon, which proved to be an adenocarcinoma on microscopic examination. The tumor was adherent to the left ureter necessitating division and ligation of the ureter. A diverticulum of the bladder also was excised. Thirty (30) centimeters of colon was removed, the bowel and tumor weighed 440 grams. Colonic continuity was established by oblique end-to-end anastomosis. The patient was dismissed from hospital 20 days later and returned for closure of the colostomy on July 28, 1943.

In August 1944 the patient returned because of the presence of a large tumor in the abdominal wall near the umbilicus. About a year previous to the decompressive colostomy done here for acute obstruction the patient had undergone repair of a large umbilical hernia elsewhere with excision of the umbilicus. On August 18, 1944 I operated upon the patient again for excision of the abdominal wall tumor believed to be an implantation transfer of malignancy to the abdominal wall, during excision of the carcinoma of the pelvic colon.

A good portion of the abdominal wall had to be sacrificed and a loop of small intestine was also excised. The abdominal wall could not be closed satisfactorily owing to the large defect occasioned by excision of the abdominal wall tumor. On microscopic examination, the growth proved to be a desmoid tumor. The desmoid tumor weighed 375 grams and measured 8 by 7.5 by 6.5 centimeters.

A large hernia resulted (Fig. 1). The patient was operated upon for repair of this defect on March 9, 1945. The defect was very large measuring 24 by 18 centimeters. The hernia was repaired by the method illustrated in Figure 2. Intimate adherence of a loop

From the Department of Surgery, University of Minnesota Hospitals, Minneapolis.

of small intestine to the lower margin of the hernial sac necessitated sacrifice of a loop of small intestine approximately 15 centimeters in length. Intestinal continuity was restored by oblique end-to-end anastomosis. Soon after the start of the operation and frequently throughout the procedure the patient's pulse was often very slow; on one occasion it was counted over a period of several minutes at 32 beats per minute. When the pulse was slow the blood pressure also was usually low, frequently as low as 70 centimeters mercury. The cause of this phenomenon remained obscure. A cardiogram made directly after operation failed to indicate any evidence of coronary disease. This queer behavior of the pulse and blood pressure may have been due to the cyclopropane anesthesia which was employed in all the procedures. I am inclined to believe, however, that it was a vagus effect occasioned by manipulation of the intestine—a circumstance which I have observed previously, particularly when the intestine is distended.

The patient did well and left the hospital on March 20, 1945, 11 days after operation. Subsequent examinations indicate that the abdominal wall is strong and firm with no suggestion of a defect or recurrent hernia. Recent photographs indicate that the functional result is excellent (Figs. 3 and 4). There is no evidence of recurrence of the desmoid tumor or of the cancer of the colon.

TECHNIQUE

In the instance herein recorded a large flap of the fascia covering the entire right rectus muscle and the greater portion of the left rectus muscle also was delineated. The dissection was begun just below the most lateral extent of the hernial defect on the left, the incision extending vertically downward to the pubis. On the right side the fascial flap contained a good portion of the external oblique aponeurosis as well. The flap was mobilized from below upward but not quite to the lower edge of the hernial defect. At the right extremity of the hernial defect muscular fibers of the external oblique muscle were present in the mobilized flap. In the lower abdomen the dissection was carried laterally to bare the spermatic cord in the inguinal canal.

This fascial flap, pedicled from its attachment at the inferior margin of the hernial defect, was quite adequate to cover the hernial opening. A large portion of the patient's small intestine had been contained in the hernial sac. In freeing the adherent loops of bowel the peritoneal surface of one segment of jejunum was traumatized enough to suggest

Fig. 1. Photograph of patient, Mr. L. I. Underst, Hospital No. 724005, before operation. a, b and c, Views of hernia in upper abdomen from various directions.

the necessity for resection of the segment followed by an oblique end-to-end anastomosis. The fascial flap was sutured in place with interrupted sutures of fine silk (No. 000).

On completion of this procedure the iliothoracic tract of fascia lata pedicled on the tensor fascia femoris muscle was mobilized from the anterolateral aspect of the right thigh as shown in Figure 2. This technique has been described in detail elsewhere. () A fairly large subcutaneous tunnel was established

Fig. 2. Schematic drawings indicate the steps in the operative repair of the hernia shown in Figure 1. a. The defect immediately below the right costal margin, measuring 8 by 24 centimeters. A pedicled musculofascial flap is swung up from the lower abdomen to fill in the upper abdominal defect. The flap consisted of the entire anterior rectus sheath beneath the umbilicus, together with portions of the external oblique aponeurosis and fibers of the right external oblique muscle. b. The iliotibial tract and its lateral extension of fascia lata demarcated as a flap. c. The fascial flap from the lower abdomen is swung into the abdominal defect. The pedicled flap from the thigh is ready to be brought over Poupart's ligament into the abdominal wound. d. Both flaps have been sutured in place.

over Poupart's ligament to permit drawing the fascial flap into the abdominal wound.

Prior to operation it had been ascertained that the distance from the greater trochanter to the upper margin of the hernial defect was

36 centimeters. The greatest possible mobilizable length of iliotibial tract of fascia below the greater trochanter was only 31 centimeters. Obviously the pedicled iliotibial tract could not be made to reach to the upper margin of

Fig 3

the hernial defect. It did suffice nicely, however, to cover the entire fascial defect in the lower abdomen created by swinging the first pedicled fascial flap.

REPLACEMENT OF INFRAUMBILICAL MUSCULO-TENDINOUS PORTION OF THE ABDOMINAL WALL BY A SINGLE PEDICLED FASCIAL FLAP

The earlier presentation concerned itself primarily with the management of recurrent and difficult inguinal and femoral hernias (1934) by means of a pedicled fascial flap from the thigh. It is desired to record here, with the instance of a boy of 15 from whose lower abdomen a large desmoid tumor weighing 1500 grams was removed. In the removal of the tumor it became necessary to excise the greater portion of the musculotendinous structure of the infraumbilical portion of the abdominal wall. This large defect was closed easily and satisfactorily by swinging up the iliotibial tract of fascia lata which was pedicled on the tensor fascia femoris muscle and was re-enforced by lateral extensions of the fascia lata.

E. B. University Hospital No. 686592 admitted to the University Hospital on October 23, 1939. Preoperative diagnosis: large abdominal tumor.

Fig 4.

Fig 3. Photographs made while the patient was still in hospital. a, The abdominal incision. b, The thigh incision.

Fig 4. Photographs made 5 months after operation. a, The abdominal wall is strong; there is no evidence of a fascial defect or hernia. b, The thigh incision.

The patient, aged 15 years, gives a story of operation for acute suppurative appendicitis about 3 years previously. The three old scars on the abdominal wall shown in the photograph (Fig. 5) indicate the sites of drainage at the time of appendectomy. He said that his abdomen enlarged gradually, but his father was not aware of it until just before admission, when he took his son to a local physician who referred him here for operation. The tumor appeared to be in the abdominal wall. On rectal examination the tumor mass could be distinctly felt. A cystogram was made which showed a definite indentation of the bladder on the anterior abdominal wall, the bladder being pushed distinctly posteriorly. It was obvious that this would necessitate an enormous operative procedure to excise it, yet in the light of previous experience with large defects in the lower abdomen it did seem worth while to undertake excision of the tumor. Closure of the defect, it was believed, could be effected by the use of a fascial flap from one or both legs.

Operation was done on October 25, 1939, under intratracheal cyclopropane anesthesia. A vertical skin excision was made in the midline extending from the umbilicus to the pubis, also a vertical incision on the lateral aspect of the thigh from just beneath the anterior superior spine to above the knee.

At operation there was found an enormous tumor which filled the entire pelvis, pushing the bladder posteriorly. There was an indentation on the tumor from pressure on the bladder. The tumor arose apparently from the rectus fascia in the lower abdomen and from the pubis. The removed tumor weighed 1500 grams.

TECHNIQUE

Through the aforementioned vertical incision the tumor was gradually exposed. It was found to lie on the parietal peritoneum. The only site at which the abdominal cavity was opened was at the umbilicus. A slip of gut came up into the wound where the gut

Fig. 5

Fig. 5. Preoperative photograph of D. B. aged 5. University Hospital No. 686593. a and b, The large protuberance caused by the desmoid tumor of the abdominal wall. c, Indicates the posterior displacement of the bladder caused by the tumor. d, The tumor.

was apparently attached to the umbilicus. The infraumbilical portion of the rectus muscles, including the anterior and posterior sheaths of both recti; the external oblique aponeurosis as well as the internal oblique, except for the musculotendinous portion of the abdominal wall lateral to the vas deferens and spermatic cord on each side was sacrificed. The abdominal wall was undercut above the umbilicus and a bit of the rectus muscles and sheaths extending above the umbilicus had to be excised. The resultant defect constituted a large area extending from the pubis below to about an inch above the um-

Fig. 5c

bilicus superiorly. The only portion of the lower abdominal wall remaining intact lay lateral to the spermatic cord on either side.

At this juncture a large flap of fascia including the iliofemoral tract of fascia in the middle and the extensions of the fascia lata covering the sartorius medially and the biceps femoris laterally pedicled on the tensor fascia femoris muscle, was brought up beneath Poupart's ligament and sutured into the defect. As the

Fig. 5d.

operation was begun. It was thought that fascia from both thighs might be necessary. The generous unilateral fascial flap however, proved quite adequate to close the defect. The musculotendinous defect into which the fascial flap was swung was 15 centimeters long and 13 centimeters wide. Because of the large persisting space overlying the bladder occasioned by the removal of the tumor it was thought well to leave a small drain in the prevesical space. The patient stood this prolonged operative procedure well and left the table in good condition. No attempt was made to close the fascial defect in the thigh; the skin edges merely being coaptated with fine silk sutures. He was dismissed from hospital on November 29, 1939.

The pathological diagnosis (Dr. Robert Hebbel) follows:

The specimen consists of a sharply demarcated somewhat lobulated mass measuring 14 by 15 by 12 centimeters. There are some attached portions of fascia and skeletal muscle. On section the tumor is fibrous and moderately firm. Centrally there is a large cystic area 7.5 centimeters in diameter which is filled with slightly mucoid fluid. The mass weighs 1500 grams.

Microscopic examination shows that for the most part cells are small and separated by an abundance of intercellular material. In a few areas and particularly in a section of a fragment removed separately from just above the penis the cells are more plump and present a greater amount of cytoplasm.

Conclusion: Fibrosarcoma, grade I of desmold tumor of the abdominal wall.

This boy, now 21 years of age, has been observed periodically in the outpatient clinic since the time of his operation in October, 1939. The abdominal wall is strong; there is no evidence of recurrence of the tumor and there is no hernia. He is able to do heavy work but was rejected for military service because of the history of the abdominal wall tumor. Shortly after the initial operation my colleague Dr. Arnold Kremen, now on military leave, examined the literature of desmold tumors. He told me that this tumor weighing 1500 grams was the largest desmold tumor removed surgically on record since 1900.

SUMMARY

A method is described for increasing the range of utility of the iliotibial tract of fascia pedicled on the tensor fascia femoris muscle

Fig. 4. A photograph made in June 1945 more than 5 years after the operation. The abdominal wall is strong and there is no defect in the fascia, nor evidence of hernia. a, The abdomen. b, The incision in the thigh.

in the repair of abdominal hernias. By employing the pedicled iliotibial tract as a replacement for a pedicled fascial flap swung up from the lower to the upper abdomen any hernia of the abdominal wall becomes amenable to treatment by this method. Heretofore incisional hernias with large defects in the upper abdomen have been difficult problems to resolve by any of the available methods. The procedure herein described gives promise of constituting a means of dealing satisfactorily with large defects of the upper abdominal wall. The method possesses the advantage over free fascial grafts of insuring satisfactory wound healing.

The instance of a patient having a defect 24 centimeters long and 18 centimeters in width in the upper abdomen following excision of a large desmold tumor of the abdominal wall is reported. A good firm abdominal wall resulted. A nonirritative nonabsorbable suture such as fine silk is the suture material of choice for anchoring the pedicle graft.

An instance is cited also in which the iliotibial tract of fascia pedicled upon the tensor fascia femoris muscle was employed to replace the larger part of the musculofascial portion of the abdominal wall below the umbilicus attending excision of a large desmold tumor

weighing 1500 grams. The defect was 15 centimeters in length and 13 centimeters in width. A single pedicled graft of the iliotibial tract supplemented by its lateral extensions of fascia lata sufficed to fill the defect.

Removal of such large fascial flaps from the thigh does not impair its function and is not followed by untoward effects.

ADDENDUM—

Since this paper was submitted for publication 3 additional patients have been operated upon for the repair of large abdominal defects. In the first a patient with an unusually large incisional hernia the plan of operation described herein was employed. Each of the other 2 patients presented a large carcinomatous mass in the abdominal wall following a Mikulicz exteriorization operation for cancer of the pelvic colon. The case records follow.

CASE 1 Mrs. A. E. aged 66 years University Hospital No. 601240 was admitted on September 30, 1945 for repair of a large incisional hernia following drainage of the gall bladder (long vertical right rectus incision) performed elsewhere several years previously. An unsuccessful attempt had been made before admission here to repair the hernia. The defect was enormous and extended from the pelvis to the costal margin. In extent the defect measured 26 by 21 centimeters. The scheme described in this paper was employed to close the defect. Fascial flaps from the lower abdomen constituted by the anterior rectus fascia and its lateral extensions were delineated from both sides of the long vertical defect. The upper and most lateral wing of each of these pedicled fascial flaps was swung upward to close the upper portion of the hernial defect. The longest and widest possible pedicled fascial flap was swung up from the right thigh pedicled on the tensor fascia femoris muscle employing the entire iliotibial tract of fascia. A satisfactory closure of the large defect was obtained. The abdominal wound healed kindly and the abdominal wall appears strong with no suggestion of a persistent defect. Owing to the curved nature of the incision on the thigh, a small slough occurred at the convex portion of the skin flap which prolonged the hospital stay. The final result seems to be very satisfactory.

CASE 2 Mrs. J. K. aged 66 years, University Hospital No. 757515 was admitted to the University Hospital on August 30, 1945 for a recurrent carcinoma of the abdominal wall and sigmoid colon following an exteriorization operation performed elsewhere 3 years previously. Excision *en masse* of abdominal wall and colic tumor with primary closed anastomosis. A mucocele of the appendix was excised also. A large fascial flap pedicled on the tensor fascia femoris muscle from the left thigh sufficed to fill the large abdominal wall defect. The patient was dismissed from hospital 8 days after operation. The abdominal wall is strong.

CASE 3 Mr. G. S. aged 64 years, University Hospital No. 760142 was admitted on November 14, 1945 had a large fungating cauliflower lesion in the abdominal wall. Two earlier Mikulicz exteriorization procedures had been done elsewhere for a carcinoma of the lower pelvic colon, the first 2 years prior to admission here. At operation, November 19, 1945 the major part of the infraumbilical portion of the abdominal wall was excised including the skin. There was a single large metastasis in the liver which was said to have been present already at the time of the first exteriorization operation done 2 years previously. The tumor involved the rectosigmoid area and was intimately adherent to the bladder and several coils of small intestine. There was a separate fairly large carcinoma in the midtransverse colon. The left ureter was sacrificed. The tumor of the abdominal wall was excised *en masse* with the colon and a primary closed anastomosis was effected between the proximal third of the transverse colon and the rectum 11 centimeters from the anus. The resultant abdominal defect involved all the structures of the abdominal wall including skin, fascia, muscle and peritoneum. The defect was 20 centimeters from above downward and 16 centimeters across in a horizontal direction. A long fascial flap was swung up from the left thigh which replaced satisfactorily the peritoneofascial defect. The skin was closed by a sliding maneuver. This 10 hour operation was without incident by the patient. Owing to some tension, a slough occurred in one of the skin flaps necessitating a secondary skin graft. The patient otherwise made a satisfactory convalescence and the abdominal wall is strong. At present the patient is at home awaiting re-entry for excision of the hepatic metastasis.

CHEMOTHERAPY AND CONTROL OF INFECTION AMONG VICTIMS OF THE COCOANUT GROVE DISASTER

MAXWELL FINLAND M.D., CHARLES S. DAVIDSON M.D. and
STANLEY S. LEVENSON M.D., Boston, Massachusetts

AT the time of the Cocoanut Grove disaster opinions concerning the efficacy of various forms of sulfonamide therapy in wounds and burns were still divided. Lyons (3) had reviewed the literature dealing with the rationale of local sulfonamide therapy and also the somewhat meager clinical reports then available on its prophylactic value. He observed that "the rather enthusiastic clinical adoption of local sulfonamide therapy had failed to provide factual data for analysis of the extent to which such treatment had prevented the growth of bacteria in wounds.

Such data were being accumulated at that time by the Contaminated Wound and Burn Projects sponsored by the Subcommittee on Surgical Infection of the National Research Council. The results of these carefully controlled observations were already providing evidence which served to temper considerably the enthusiastic reports brought back by some of those who had an opportunity to observe the casualties at Pearl Harbor.

Based on the evidence which was available at that time and which was subsequently confirmed and greatly amplified in Meleney's report (5) the Burns Project¹ as set up at the Boston City Hospital at the time of the Cocoanut Grove fire did not include the local use of sulfonamides. There were only 2 cases among the Cocoanut Grove victims at this hospital in which sulfonamide powder was applied locally on some occasions and 2 others in which sulfathiazole ointment was applied to some of the burned areas about the face.

From the Thorndik Memorial Laboratory Second and Fourth Medical Services (Harvard) and the Burn Unit of the Surgical Services, Boston City Hospital and the Department of Medicine, Harvard Medical School, Boston, Massachusetts.

The work described in this paper was done, in part, under a contract recommended by the Committee on Medical Research between the Office of Scientific Research & Development and Harvard University.

This therapy however played only a minor rôle in the management of these cases.

The systemic use of sulfonamides in the present cases was undertaken from two separate though similar, considerations. First with respect to the surface burns it was thought that chemotherapy might be useful in limiting infection to the burned areas and that cellulitis and septicemia might thereby be prevented. Secondly since respiratory tract involvement constituted such an important part of the injuries in these cases, the use of sulfonamides was considered to be the best available means of preventing or minimizing pulmonary infections which were expected to complicate these injuries. These indications seemed reasonable on the basis of the known clinical experience although there was very little in the way of conclusive evidence from published reports that the drugs would serve those purposes.

The administration of sulfonamides in many of the present cases involved considerable difficulties. Because of the wide differences in the general condition of the patients, in the extent of their surface burns and respiratory injuries and in other incidental complications the treatment had to be individualized and controlled with great care. The major problems arose chiefly from 3 sources namely (1) shock and its effect on the circulation and on renal function (2) impairment of renal function associated with hemoglobinuria and (3) difficulties in maintaining proper water and electrolyte balance particularly in view of the use of large amounts of plasma and the tendency on the part of some of the surgeons to avoid the administration of additional fluids. All 3 of these factors were thus focused on the one point of avoiding the most frequent of the serious complications of sulfonamide therapy namely those involving the urinary tract.

The present report comprises an analysis of the sulfonamide therapy as actually used in the cases admitted to the Boston City Hospital from the Coconut Grove fire. An attempt will be made to evaluate the results of this therapy as far as that can be done from the data available. The bacteriological findings are summarized for some of the cases in which significant infection occurred in the burned areas and in the respiratory tract. The relevant findings with respect to fluid and drug administration in illustrative cases and groups of cases will be summarized.

ANALYSIS OF THE SULFONAMIDE THERAPY USED

As already intimated neither the local nor the systemic use of sulfonamides formed a part of the program of the routine management of burns in this hospital at the time of the disaster. During the first few hours after the fire little attention was therefore paid to the problem of chemotherapy in the present cases and only an occasional patient received it orally or as part of the parenteral fluid therapy given at that time.

Selection of cases for sulfonamide therapy. During the surveys of all the patients which were made by the authors on the morning and evening after the fire and at regular intervals thereafter particular attention was paid to the problem of sulfonamide therapy. Details of the therapy prescribed depended on the state of hydration, the urine output, the ability of the patient to take medication orally and the results of blood studies. In many instances it was considered inadvisable to start therapy during the first day or two because of the low or absent urinary output, because of nitrogen retention, hemoglobinuria or for other reasons. In other patients with minor burns treatment was not given at first but was started later usually because of the respiratory tract complications.

A total of 76 patients received sulfonamide therapy. In Table I there is given an analysis of these cases with respect to the time when the treatment was begun, its duration and the total amount of drug used. The cases are arranged according to the severity of respiratory tract involvement. Sulfonamides were

not used in 24 of the fatal cases and in 31 of the survivors. The former included most of the patients who had the most extensive surface burns and were in shock at the time of arrival or shortly thereafter and also those with the severest respiratory tract damage who had symptoms of respiratory obstruction soon after they arrived. All of these patients died during the first 2 days and 15 of them died within the first 24 hours. Among the survivors who were not given sulfonamide drugs were 19 patients who were discharged or transferred to other hospitals during the first 18 hours, 4 others with minimal involvement who were discharged within 36 hours and 2 who were kept in the hospital for injuries other than burns. The remaining 6 patients had burns involving 5 per cent or less of the surface area which were not severe and were associated with minimal, if any, respiratory complications. Slight and transient fever occurred in 3 of the latter patients and that constituted the only evidence of possible infection among the patients who did not receive sulfonamide drugs.

Time of beginning treatment. Treatment was begun within the first 24 hours in 20 of the cases, during the second day in 40 cases and later in the remaining 16. Half of the cases of each of the first 2 groups had severe respiratory symptoms and the others had either moderate respiratory damage or fairly extensive burns. Only 3 of the 16 patients in whom treatment was begun on the third day or later had severe respiratory tract involvement. Two of them had no surface burns while the third had burns involving almost two-thirds of the body surface and died on the day after the drug was started. Among those with mild or moderate respiratory involvement in whom treatment was delayed 3 had burns of 20 per cent or more of their body surface. Four had burns of 6 to 8 per cent and the rest had only minor burns. In only 1 of these patients (Case 59) did it seem likely that infection of the wound contributed materially to delay in healing or to the prolonged stay of the patient in the hospital. The delay in starting treatment was usually due to the factors already outlined but chiefly to the fact that the patients had a poor urinary output.

Choice of drug Sulfadiazine or its sodium salt was used more or less routinely and this drug was given to all but 5 of the 76 patients. Sulfapyrazine was used in 2 cases and sulfathiazole in 14 but in only 1 of the former and in 4 of the latter were these drugs used alone. In the remaining cases the sulfapyrazine or sulfathiazole was given after sulfadiazine either because the patient had untoward reactions attributable to sulfadiazine or as the supply of that drug was temporarily exhausted.

Route It was considered desirable to use the oral route for administration of the sulfonamides as far as possible, this method offering the least likelihood of producing urinary tract complications. The intravenous route was used for the initial dose in some of the cases with the severest burns. In almost all such cases fluids other than plasma or blood were being given by this route and the patients were fairly well hydrated. All of the intravenous drug was given as sodium sulfadiazine dissolved in physiological saline in concentrations of 0.5 per cent or less of the drug. As far as could be ascertained, no renal complications occurred that could be attributed to the parenteral chemotherapy. An increase in the nonprotein nitrogen occurred in 2 fatal cases but in both of them hemoglobinuria, oliguria and some elevation of the nonprotein nitrogen were already present before the sulfonamide treatment was started.

Dosage The initial dose of sulfadiazine which is customarily given to adults in this hospital is 4 grams orally or 5 grams of the sodium salt when given parenterally. In the present cases since the drugs were being used chiefly for prophylaxis and also because of the greater possibility of kidney injury and of difficulties of maintaining fluid and electrolyte balance, smaller initial doses were given in many of the cases. In 8 of the patients in whom treatment was begun by an intravenous injection the initial dose was 2 to 3 grams and about one-half of those who received oral therapy were given 2 grams for the first dose. The latter was usually repeated after 4 hours. The maintenance dose was that which is customarily used, namely 1 gram every 4 hours but modifications were made from time to time as indicated by clinical and laboratory

findings in the individual cases. In a few instances the parenteral injections were repeated once after 8 to 12 hours but only 1 patient received 3 and 1 other received 4 intravenous injections. All the parenteral injections given after the first one consisted of 2 to 5 grams of the drug.

Alkalis The use of alkalis was limited chiefly to the patients with extensive burns. They were first given during the early survey of the patients because of the finding of some cases with hemoglobinuria among those who were severely burned. All of these patients in whom hemoglobinuria was detected and most of the others who had extensive burns were given alkalis at that time. They were administered in the form of sodium bicarbonate orally when possible or in the form of $\frac{1}{2}$ molar sodium lactate intravenously as a supplement to other parenteral fluids. The alkali therapy was intended as a preventive against possible renal complications. These were anticipated more because of the hemoglobinuria than from the chemotherapy although the latter consideration also entered into the decision to use the alkalis.

It must be stated however that the alkalis were not given without some hesitation. The possibility of water retention resulting from the sodium administration¹ and the consequent aggravation of the edema and exudation from the wounds or the development of pulmonary edema were considered. The finding of highly acid urine in the cases of hemoglobinuria was the deciding factor. An attempt was made wherever possible to adjust the dose so as to give a neutral or slightly alkaline urine. Usually 1 or 2 grams of sodium bicarbonate was given with each dose of sulfonamide. In most instances the alkalis were discontinued after the patient was able to take adequate amounts of fluid and to maintain a good urine output but it was stopped earlier if dependent edema developed outside of the burned areas or if the urine output continued to be small.

Duration of chemotherapy (Table I) Treatment with sulfonamides was maintained for an average of 11 days and a second course of

¹Since the plasma used was derived from citrate, all these patients had already received considerable amounts of sodium from this source.

TABLE I—ANALYSIS OF CHEMOTHERAPY AS USED IN THE CASES ADMITTED TO THE BOSTON CITY HOSPITAL FROM THE COCOA NUT GROVE FIRE

Grade of respiratory involvement	Cases	Mild/moderate	Severe	All cases
Number of patients who received sulfonamides	61	37 ^a	24	75 ^b
Sulfonamide therapy began first day		61	10 ^a	60 ^a
Second day			10 ^a	60 ^a
Third day or later			3 ^a	10 ^a
Duration of sulfonamide therapy Less than 1 day			4 ^a	4 ^a
1-7 days		8	6 ^a	14 ^a
8-14 days		9		9 ^a
15-21 days		3	10 ^a	13 ^a

101-150	5	14		19 ^a
151 or more			6	6 ^a
Average dose	67 ^a	67 ^a	17 ^a	66 ^a

The figures for the total cases are given in the superscripts.

therapy was given before and during skin grafts in a few cases and in some others because of recurrent fever. The cases in which the drug was used for 4 days or less included 9 in which death intervened and 8 in which the burns were either absent or of minor extent and severity and the respiratory damage was relatively mild. On the other hand, those in which treatment was continued for more than 2 weeks included most of the patients who had either extensive and severe burns or severe respiratory damage or both.

Total dose. The amount of drug used in each case was, of course dependent on the time over which it was given. The average total dose per patient was 60 grams which was only slightly less than 6 grams per day. This reflected the fact that, in general, full doses were maintained throughout the course of treatment. In a few instances, however

TABLE II—TOXIC EFFECTS FROM SULFONAMIDE DRUGS OBSERVED AMONG 76 CASES ADMITTED TO THE BOSTON CITY HOSPITAL FROM THE COCONUT GROVE FIRE

Toxic manifestation	No. of cases
Fever without rash	4

^aIncludes 1 with drug fever and with renal colic.
^bAll had hemoglobinuria before sulfonamide therapy.
^cIncludes case with rash.

the daily dose was reduced temporarily because of retention of water nitrogen or drug.

Blood levels. Chemical determinations of sulfonamide levels in the blood were done frequently in some cases and irregularly in others. They were carried out frequently in patients in whom difficulties were encountered in the administration of fluids and also in those having abnormal urinary findings or high blood nonprotein nitrogen levels. Some idea of the drug levels found in the blood may be had from Figure 1 which shows the concentrations of free drug observed during the first 3 weeks. For the most part, as will appear later from the data of individual cases, there was a fairly constant and small amount of acetylated drug in the blood about 1 milligram per 100 cubic centimeters in the majority of cases. The level of the free drug in the blood was most often between 4 and 8 milligrams per 100 milliliters. High levels were encountered more frequently during the first few days and low levels were more frequent after the first week. On the whole these low and irregular values reflect the difficulties in controlling the various aspects of chemotherapy in many of the patients, particularly those who were severely ill. This aspect, too will appear from the charts of individual cases.

Toxic effects (Table II). An estimation of the frequency with which toxic effects were observed in the present group is necessarily inadequate. Some of the untoward manifestations were undoubtedly masked or went unobserved for one reason or another. In addition it was difficult to determine whether or not certain manifestations were attributable

Fig. 1. Concentrations of free sulfadiazine in blood in Coconut Grove cases.

to the toxicity of the drug. Thus there were 3 cases in which blood nonprotein nitrogen levels rose early in the course of therapy but in each case hemoglobinuria oliguria and abnormally high levels of nonprotein nitrogen were noted before the drug was first given.

There were 7 cases in which fever could be attributed definitely to drug toxicity. In 3 instances this fever was associated with a scarlatiniform or morbilliform rash (with epidermitis in one of them) which appeared on the fifth day in one case on the seventh day in another and on the eighth day of the second course of treatment in the third case. In the latter the same drug (sulfadiazine) had been given for 23 days during the first course and an interval of 3 weeks had elapsed before the second course was started. In each of these 3 cases the rash subsided when the sulfadiazine was stopped although sulfathiazole or sulfapyrazine was used to continue the treatment without interruption. Drug fever unaccom-

panied by a rash began on the 10th, 11th, 12th and 20th days respectively, of sulfadiazine therapy. In each of the 4 cases the fever subsided within a day after the sulfadiazine was discontinued and in one of them sulfapyrazine was used to maintain chemotherapy without interruption. In one other patient a second course of sulfadiazine was given after an interval of 10 days and full doses were given for 5 days without a recurrence of the fever.

Urinary tract complications were observed in 5 cases in addition to the 3 with the nitrogen retention which have already been mentioned. Microscopic hematuria was the only manifestation of this complication in 3 cases. It was observed on the 7th and 9th day and was not accompanied by crystalluria. In the fourth case gross hematuria with dysuria occurred on the third day and cleared rapidly when the fluid intake and output were increased. In the fifth case there was renal colic accompanied by microscopic hematuria on the fourth day.

TABLE III — ANALYSIS OF THE OCCURRENCE OF FEVER IN CASES ADMITTED TO THE BOSTON CITY HOSPITAL FROM THE COCONUT GROVE FIRE

Analysis of fever	Sulfonamide therapy				Total

*100°F or higher

and this cleared within a few hours following intravenous fluid administration

Severe nausea was attributed to sulfadiazine in one case and vomiting was attributed to sulfathiazole in another. These symptoms began early and cleared rapidly when the drug was stopped. Leucopenia was encountered in 2 cases. In Case 47 the white blood cell count was 4,000 on the thirteenth day which was 1 day after the drug had been stopped. In Case 54 the total white count was 2,000 on the twelfth day 2 days before the drug was stopped. The count in this case rose to 16,000 on the fifteenth day without any special treatment directed at the leucopenia. The total dose used was 54 grams in 12 days in the former and 79 grams in 14 days in the latter. In neither of these cases was the percentage of granulocytes depressed.

On the whole, therefore, it may be said that the incidence of untoward effects of chemotherapy was very low. Excluding the cases of hematuria and the 1 case of colic these toxic effects were not serious. It is possible of course that other minor toxic effects were overlooked or that some of the symptoms ascribed to other factors may have been due to the drug. It is fair to say, however, that more serious complications and larger numbers of them were probably avoided by careful vigilance.

RESULTS

Any attempt to evaluate the effects of chemotherapy in the prevention or control of infection in the present group of cases must of necessity be little more than an expression of opinion or of impressions. Even the estimation of the presence, extent and severity of infection was beset with considerable difficulties. As to the burned surfaces, their appearance, odor and the presence of purulent exudate containing bacteria, or the development of lymphangitis or cellulitis in the vicinity of the burns were relied upon to give evidence of infection. The significance of that infection, however, could not readily be determined in each instance. Healing apparently proceeded rapidly in spite of such infection in many of the cases with superficial burns, while in others particularly in third degree burns the

infection undoubtedly contributed to the development of malnutrition and also considerably delayed the healing process. With regard to the pulmonary lesions also it was not possible to determine in most instances to what extent the physical signs and x ray findings were the result either of the original injuries or of superimposed infections.

In order to obtain some idea as to the amount of infection present in these cases some of the objective findings will be summarized. The occurrence of fever and leucocytosis at various intervals after the injuries will be analyzed from that point of view. The available bacteriological findings will be presented and correlated with the other evidences of infection.

Fever An analysis of the occurrence of fever in the patients who were in the hospital for 18 hours or longer is given in Table III. Of the 101 patients in whom data were available only 10 remained completely afebrile. One of these 10 patients died during the first day but the others had only minor surface burns or respiratory injuries. Only 1 of the latter cases received chemotherapy and this was given only during the first day.

Fever occurred very early in most of the cases with moderate or severe burns and in those with respiratory damage. In 85 of the 91 patients who had fever at some time during their course, an elevation of temperature to 100 degrees F or higher was recorded during the first or second day. In almost every instance the fever was associated with surface burns of varying extent. This early appearance of fever can hardly be attributed to infection. It did, however, contribute to the difficulties in recognizing the presence of infection which may have occurred during the first few days. The fever was usually of short duration. In about two-thirds of the cases it lasted for 4 days or less but the proportion of patients having such a short febrile course was smaller among the survivors and somewhat higher among the fatal cases, many of whom died during this period. In most of these cases infection probably played only a minor rôle. In the remaining cases the fever was probably due to infections which usually were limited to the burned surfaces.

The 8 patients who had fever for more than 2 weeks are of interest. In 6 of them the burns involved 20 per cent or more of the body surface. Of the 2 remaining patients one (Case 68) had burns involving only 5 per cent of the body but some of the areas were deep and badly infected. This patient had no respiratory tract involvement. In the other patient (Case 22) on the other hand, the surface burns were relatively clean but there was marked respiratory injury with massive atelectasis of the left lower lobe and probably pneumonia superimposed in that lobe, and these were very slow to clear. In very few other cases could persistence of fever be attributed solely to respiratory tract infections.

In all of the fatal cases there was fever throughout most of the first few days except in those patients who died very early. Among those who recovered and were treated with sulfonamides the proportion of patients having fever dropped progressively from 92 per cent in the first 2 days to 54 per cent during the third and fourth days and 43 per cent during the next 6 days. Among the 13 patients who recovered but did not receive sulfonamides only 5 had any fever. These patients however had only minor surface burns and no respiratory tract involvement and in no instance did their temperature rise above 101 degrees F.

The maximum temperatures observed were usually not very high. In more than half of the cases it was less than 102 degrees F and in all but 12 of the remaining cases it was below 104 degrees. Those in whom the temperature rose to 104 degrees or higher are of special interest. Of the 8 who had such high fever during the first 48 hours only 1 survived. This was a patient (Case 24) with a burn of 14 per cent of the body and a moderately severe (Grade 3) respiratory tract involvement. There was infection of the burned area later in this case but probably little if any infection of the respiratory tract, and the temperature levels were lower after the second day. The remaining 7 patients all died before the end of the second day. The temperature before death reached 106 degrees in 2 of them, 107.5 degrees in the third and 109 degrees in a fourth.

TABLE VI.—BACTERIOLOGICAL FINDINGS IN THE INFECTED SURFACE BURNS IN RELATION TO SULFONAMIDE THERAPY

Case No.	Per cent of surface burned		Chemotherapy			Day of culture	Blood S.D. level	Location of infected burn	Organisms found

*This patient died on the 18th day. Many blood cultures taken during life were negative. B co was cultured from the lungs at autopsy. Explanations and abbreviations.

For definitions of grades of respiratory involvement see Table I.

Days—days after admission (New York day; etc.)

Blood S.D.—blood concentration of free sulfathiazole in mg./100 ml. on day culture was made (or within day) —not done

Sputum: smc = mucoid, pur = purulent; epth = epithelial; squa = squamous; col = coloniform; B S = blood streaked; plug = cells showing phagocytosis of bacteria.

Bacteriology: Str = non hemolytic streptococci; Str a = alpha hemolytic streptococci; Str β = beta hemolytic streptococci; Ps = pneumococcus (type given in Roman numerals); No./M.P.P. = number of encapsulated pneumococci per high power field as seen in Neufeld preparations.

B co = coagulase positive, hemolytic, staphylococcus aureus
H inf = Haemophilus influenzae
B pyoc = Bacillus pyocyaneus
M. col. = Micrococcus catarrhalis
O — gram negative
Percentages shown represent an estimate of the relative numbers on surface cultures (and smears) has not mentioned, the organisms are listed in the order of their relative frequency
B co all were classified as B. coli communis
B. M. C. = Bacillus mucosus capsulatus (Friedlander's bacillus)

hemolysis while in others the alpha hemolytic streptococci occurred independently. The Friedländer's bacilli were all identified as Group B.

Blood cultures were taken during the febrile course in many of the cases and most of them were sterile. *Staphylococcus albus* was recovered from blood cultures in 2 cases, diphtheroids in 1 case and gram negative bacilli in 3 others. The significance of these findings is not certain but the organisms were considered at the time to be contaminants since other blood cultures in the same cases were negative. In Case 131 cultures of the infected wounds were not made but pyocyanous bacillus was obtained from a culture of the blood on the eighth day. Earlier and later blood cultures in this case were negative.

Bacteriology of the sputum. Bacteriological studies of sputum were made on 1 or more occasions in 13 cases including 3 in which cultures were also made of the wounds. In 10 of the cases there were severe grades of respiratory involvement. The sputum specimens were obtained from the patients after the mouth and pharynx were cleared by rinsing and gargling with tap water. They were taken directly to the laboratory where they were streaked on the surface of blood agar plates grown in blood broth and injected into mice. Gram and Wright stained smears were made directly from the sputum and Neufeld typing was carried out when organisms resembling pneumococci were seen. In contrast to the wound cultures those of the sputum were made during the first 2 weeks and while the patients were still receiving sulfonamides. The character of the sputums and the results of the bacteriological studies are listed in Table VII together with a summary of the significant features concerning the chemotherapy employed in the cases.

Most of the sputum specimens obtained early were quite scant mucoid and slightly purulent, and smears showed numerous squamous and sometimes ciliated epithelial cells. Some of the later ones were frankly purulent and had either a yellowish greenish or chalky appearance. In 4 cases, some of the specimens were either rusty blood streaked or pink in color due to admixture of blood.

As was the case in the wound cultures the organism found with the greatest regularity and in the greatest numbers in the sputum was *Staphylococcus aureus*. This organism was cultured from almost every specimen obtained from 12 of the cases and it was the predominant organism found in many of these cultures. All of the strains were hemolytic and produced coagulase.

The streptococci obtained from the sputum were predominantly alpha hemolytic, and some nonhemolytic strains were also found. These were considered to be part of the normal mouth flora although in some instances they constituted one half or more of the colonies that grew in the direct cultures on blood agar plates. Beta hemolytic streptococci were obtained only in Case 36, but although they appeared in considerable numbers there was no clinical evidence of anything which could be interpreted as a hemolytic streptococcal infection in this case.

Pneumococci were obtained in significant numbers in 5 cases. In 3 of them types III, VIII and XXIV pneumococci were obtained only in the first specimen and in 1 case type IV pneumococci were obtained in the first 2 specimens of sputum and no pneumococci could be found in any subsequent specimens. In the fifth case type XXII pneumococci were identified in large numbers in 4 of the 5 specimens studied. In some instances the pneumococci showed evidence of drug action in the stained smears made directly from the sputum. From each of the specimens containing pneumococci other organisms, particularly staphylococci were also obtained in large numbers.

Influenza bacilli were identified in one or more specimens from 4 cases and miscellaneous other organisms were also encountered either in the smears or in the cultures.

The significance of any of these organisms and the part which they played in pulmonary pathology cannot be stated with any degree of certainty. The purulent character of the sputum in some of the cases strongly suggested that the *Staphylococcus aureus* which was so abundant was actually active and contributing to the necrotizing character of the lesions already present in the trachea and bronchi and possibly also in the lungs. I re-

TABLE VII.—BACTERIOLOGICAL FINDINGS IN SPUTUM IN RELATION TO CHEMOTHERAPY

Case No.	Grade of respiratory involvement	Chemotherapy			Day of culture	Blood S.D. level	Description of sputum	Bacteriological findings

Blood culture on 10th day—B. pyoc.

sumably the pneumococci also played a rôle in some of the cases.

As already indicated, it was difficult to determine the part played by infection in the abnormal physical and x ray findings in the lungs. In many of the cases with extensive signs fever and leucocytosis probably resulted from the skin lesions. This was particularly true in those cases in which infection of the

burned areas was apparent. Most of the patients with extensive pulmonary lesions had fever and leucocytosis during part of their course and, with few exceptions, these evidences of infection improved with the healing of the surface burns. On the whole considering the extensive amount of respiratory damage present at the time of admission in this group of cases, it may be stated categorically

that infections of the respiratory tract were relatively few and generally mild. Further more, it seems reasonable to ascribe this comparative mildness and infrequency of the respiratory tract infections to the chemotherapy which these patients obtained during the first week or two in the hospital.

There was also every reason to believe that none of the patients died primarily as a result of infection of the respiratory tract. There is one possible exception. This was a patient (Case 110) with severe and extensive burns who seemed much improved after 3 weeks of a rather stormy course. He was then transferred to another hospital for skin grafting and further care. He had no clinical evidence of pulmonary involvement when he left the hospital and x rays at that time showed his lungs to be essentially clear. Soon after he arrived at the other hospital he developed high fever and respiratory distress and died 6 days later. Autopsy in this case showed an extensive necrotizing type of staphylococcal pneumonia and evidence of the underlying tracheobronchial damage which was similar to that found in other cases. Definite evidence of early confluent staphylococcal pneumonia was also present in Case 107. In this case a tracheotomy was performed early and death occurred on the seventh day and resulted from respiratory obstruction. In the other fatal cases infection played only a minor rôle in the pathology of the respiratory tract as found at autopsy.

CASES ILLUSTRATING THE USE OF CHEMOTHERAPY

It has already been indicated that the urgent needs of patients made it difficult and at times impossible to make and record a considerable number of observations which would have been useful for the purpose of evaluating many important features of the various types of cases encountered. This is particularly true with respect to the evaluation of the results of the various therapeutic agents and procedures used. After the initial phases however a number of studies were made and some of them are of interest in spite of the paucity of earlier data. Because of the peculiar problems presented in the administration

of sulfonamides in many of the cases from the Coconut Grove fire studies of this aspect were undertaken in representative cases as soon as it became feasible. The results of the studies will be presented by summarizing the findings in characteristic cases in which there were various combinations of surface burns and respiratory injuries of different degrees of severity. The data in these cases will be shown in the accompanying figures.

Cases of hemoglobinuria and impaired renal function. Among the first problems encountered during the initial survey of the cases for the purpose of outlining a program of chemotherapy were the scant urinary outputs and their association with hemoglobinuria in a few of those who were most severely burned. As already stated, this finding prompted the use of alkalis which were given at the time with the view of preventing or minimizing renal complications from that source. This procedure seemed justified because of the high acidity of the urine in these cases but the possibility of water retention was borne in mind. Attempts were therefore made to keep track of the fluid balance as far as possible. It was the finding of hemoglobinuria and oliguria which prompted the excessive caution and delay in initiating sulfonamide treatment in some of the cases at least until alkalis had been given and a reasonable output of urine assured.

Details concerning the hematologic and other interesting findings in these cases as well as studies dealing with the mechanism of hemoglobinuria are given in the paper by Shen Ham and Fleming. Most of the Coconut Grove cases in which this complication was recognized died early. The observations relevant to the chemotherapy in 4 of the fatal cases with hemoglobinuria in which death occurred on or after the fourth day are shown in Figure 2 and the findings in the only patient admitted from this fire who survived this complication are shown in Figure 3. Each of these 5 patients had burns which involved 45 per cent or more of their body surface and were mostly third degree. Shock was present on admission in Cases 119, 125 and 131 while in others it was averted in the early phases by vigorous treatment with plasma and fluids.

Fig. 2. Findings in 4 fatal cases with hemoglobinuria. A, Case 31; B, Case 119; C, Case 120; D, Case 131.

During the first 24 hours each patient received between 3 and 5 liters of fluid mostly by the intravenous route in addition to the large amounts of plasma. Large amounts of fluid and varying amounts of plasma were also given during the succeeding days. Only 1 of these patients, however, excreted a significant quantity of urine during the first day (Case 38 Fig. 3) and he continued to maintain

a fairly good output. In Case 125 (Fig. 2D) there was a good output of urine on the second day and thereafter. In Case 119 and Case 120 (Figs. 2B and 2C respectively) the output continued to be small while in Case 131 (Fig. 2A) it improved steadily over a period of 4 days.

Sulfadiazine was started at the end of the first day in Case 119 during the second day in Cases 125 and 131 and early in the third day

Fig. 3. Findings in Case 38 in which there were extensive burns, hemoglobulinuria, and recovery.

in Cases 38 and 120. The initial dose was given intravenously except in Case 38. Treatment was not continued in Case 120 because of the poor condition of the patient and the failure to establish a good urine flow. The rest of the treatment varied in different cases as shown in the charts.

There was an elevation of the blood nonprotein nitrogen in all but 1 of these cases and

this finding contributed to the caution observed in the administration of the drug. It is interesting to note, however, that this abnormality was not associated with excessive drug retention or with a high degree of acetylation of the drug in the blood, except temporarily in Case 131. In that case and also in Case 125 the blood nonprotein nitrogen remained elevated at a fairly constant level over several

Fig. 4. Findings in 3 fatal cases. A, Case 128 B Case 113 C, Case 107

days while in Case 38 the level dropped progressively to normal. Moderate blood sulfadiazine levels were maintained in each of these cases but it was necessary to reduce the dose to avoid excessive drug retention in Case 131.

Fever, tachycardia, and leucocytosis were present in each of these cases. In 3 of the fatal cases there was a steady increase in the respiratory rate. All of those patients who died had extensive tracheobronchial and pulmonary lesions but evidence of some bronchopulmonary infection was found at autopsy only in Case 131. There was definite infection of the wound in Case 131 and in Case 38.

Other fatal cases. The findings in 3 other fatal cases of different types are shown in Figure 4. All of these patients were in shock during the first few hours in the hospital. In Case 107 (Fig. 4C) there was a burn of moderate severity involving 12 per cent of the body surface but there was marked tracheobron-

chial obstruction necessitating early tracheotomy, frequent aspirations and the continuous administration of oxygen which, from time to time, was given under positive pressure. These procedures gave only partial and temporary relief. In each of the other 2 cases there were extensive and severe burns involving an estimated 30 per cent of the body surface. In Case 128 there were no abnormal physical signs or symptoms referable to the respiratory tract, while in Case 113 there was considerable respiratory distress without any definite symptoms of obstruction.

In each of these cases there was only a small urine output during the first 24 hours in spite of the administration of moderate amounts of fluid. Sulfadiazine was begun at the end of the first day in Case 107 and early in the second day in Cases 113 and 120. The intravenous route was used for the initial dose and for an occasional follow-up dose in the latter 2

Fig. 5 Findings in 2 cases with fairly extensive burns and recovery A, Case 15 B Case 28.

cases whereas oral doses were used throughout in Case 10.

Slightly elevated nonprotein nitrogen levels were found only in Case 113. Drug concentrations were maintained at a low level in Case 128 and at moderate levels in Case 107 while the initial levels were low and increased gradually in Case 113. There was some difficulty in maintaining good urine output during the first days in each case. There was probably some water retention in Cases 107 and 113 during the last 2 or 3 days. This was evidenced by the finding of dependent edema.

There was only minor infection found in the lungs at autopsy in Case 113 and some confluent bronchopneumonia in Case 107 but both had rather extensive tracheobronchial and pulmonary pathology. In Case 128 death occurred on the eighteenth day and was attributable to malnutrition. The lungs in that case remained clear throughout but there was

considerable infection of the wound off and on after the first 2 weeks.

Cases of fairly extensive burns and recovery
The findings in Cases 15 and 28 are shown in Figure 5. In the former the burn involved 20 per cent of the body surface and in the latter it involved 28 per cent and the patient was in shock at the time of admission. A good fluid balance was readily established in both of these cases. They both had only minor respiratory involvement and this was limited mostly to the upper respiratory tract.

Sulfadiazine treatment was started early in the second day in Case 15 and during the third day in Case 28 and all the therapy was given orally. In the latter patient the therapy was maintained for about a week while in the former it was given with interruptions over a 2 week period. Low grade infection developed in the wounds during the latter part of the treatment and persisted for several weeks in

Fig. 6. Case 1

both of these cases. The respiratory tract, however, remained free of infection as far as could be determined.

Cases of severe respiratory tract damage and surface burns of moderate extent. The data in 3 such cases Cases 11, 23, 24, are shown in Figures 6, 7 and 8 respectively. The burns involved 16 per cent of the body surface in Case 11, 6 per cent in Case 22 and 14 per cent in Case 24. While a small part of the burns were deep in the first 2 cases, most of the involved areas in Case 24 proved to be third degree burns. None of these patients were in shock. Each of them received 2.5 to 3 liters of fluid in addition to plasma during the first 24 hours. There was a small output of urine during that period in Case 24 but each of the

others excreted more than a liter during that time.

Full oral doses of sulfadiazine were started shortly after admission in Case 11 and on the second day in the other 2 cases. This treatment was maintained for more than 3 weeks in 2 of the cases while in Case 22 it was interrupted after 2 weeks and then given again for a few days after an interval of a week. The blood levels in these cases remained fairly low most of the time. This may have been due in part, to the fairly large amounts of fluid taken by these patients throughout most of this period. There was no significant increase in the blood nonprotein nitrogen in any of these cases.

Each of these 3 patients had some fever and elevated pulse rate. The fever was low grade

Fig 7 Case 22

and declined steadily during treatment in Case 11 and the patient raised some purulent and rusty sputum containing staphylococci pneumococci and influenza bacilli (Table VII). During this time there were diffuse musical and crepitant rales limited mostly to the lung bases but there were no extensive areas of consolidation. There was also slight infection of the wound which was first noted during the latter part of the second week. In Case 22 the temperature and pulse rose during the latter half of the first week and remained elevated for 2 weeks. During this period there

were definite signs of consolidation and massive atelectasis of the left lower lobe and the patient raised moderate amounts of mucopurulent sputum containing many pneumococci and staphylococci (Table VII). The physical signs and abnormal x ray findings persisted for more than 4 weeks and cleared only gradually thereafter. There was no definite infection of the surface burns.

In Case 24 on the other hand there was moderate infection in the deeper burns. This was accompanied by fever and leucocytosis which began during the end of the first week.

connection with its topical use but it has either been taken for granted or ignored by most observers with respect to systemic administration of the sulfonamides. The latter too requires careful and individualized attention to details if one is to use these drugs intelligently and be able to assess their true value. These difficulties and the failures of chemotherapy with the sulfonamides which are now available justify a continuation of the efforts to obtain less toxic and more readily controllable as well as more effective agents.

In the present cases it is not possible to give any true evaluation of the effect which chemotherapy had in preventing or limiting infection. There are of course no controls for comparison. Indeed there are few similar groups of cases with which such comparisons can be made. At the Massachusetts General Hospital emphasis was placed on strict aseptic technique and eschar producing agents were scrupulously avoided. In this hospital on the other hand aseptic precautions were not rigidly enforced and tanning agents and dyes were applied to the burned surfaces in many of them. Nevertheless, the frequency and severity of the wound infections were apparently quite similar in the Coconut Grove cases at both institutions. Whether or not infection of the wounds would have been more severe had sulfonamides not been used at all can only remain a matter of conjecture. The almost complete absence of septicemia, lymphangitis and extensive cellulitis beyond the confines of the burned areas in spite of the extensive and severe lesions may probably be attributed in part at least, to the systemic use of these drugs. Local infections limited to the burned surfaces on the other hand were certainly not prevented. In this respect the results are similar to those obtained under the more carefully controlled condition in the study summarized in Meloney's report (5).

With respect to the respiratory injuries, on the other hand the comparatively small number of severe pulmonary infections can probably be attributed directly to the use of the sulfonamides. The fact that so few of the patients with severe respiratory damage died after the first few days coupled with the additional fact that those in whom death

occurred after the first 2 or 3 days, had extensive surface burns, can be taken as an indication that pulmonary infections were kept in check. It may be expected that the sulfonamides might have a similar beneficial effect in preventing or controlling the late infectious complications of other pulmonary irritants such as those used in chemical warfare or those sometimes encountered in industry. In 2 other disasters in which respiratory tract complications occurred from fire or irritants or both, pulmonary infection was a major factor in all of the deaths which occurred after the first 2 to 3 days (2, 7).

The organism which was most frequently encountered in the infections of both the wounds and the respiratory tract was *Staphylococcus aureus*. Most strains of this organism are only slightly susceptible to sulfonamides. Prolonged treatment with the maintenance of high blood levels are therefore probably essential if infection with these organisms are to be controlled. Once the necrotizing action of these organisms has occurred and purulent foci become established, such treatment, if successful probably serves only to limit the spread of infection until the exudate is evacuated or local healing takes place. The low sulfonamide blood levels generally obtained both in the cases at this hospital and in those at the Massachusetts General Hospital as well as the failure to pursue the treatment adequately may have been important factors in limiting or minimizing the effectiveness of the sulfonamide drugs. The reasons for the failure of sulfonamides to control the growth of bacteria in surface wounds have been adequately discussed by Lyons (3) and Meloney (5) among others.

It is possible that penicillin would have been more effective in many respects. Even with this agent, however it is now recognized that small doses such as those used at the Massachusetts General Hospital are totally inadequate even for prophylaxis of infection when the *Staphylococcus aureus* or the other usual wound contaminants are concerned. Larger and more frequent doses may be more effective but this still remains controversial (1, 6). It is of interest that even hemolytic streptococci were grown from some of the

wounds in spite of the use of sulfadiazine at both institutions and the added use of penicillin at the Massachusetts General Hospital. Larger doses of penicillin might have been expected to prevent the growth of this organism in the wounds.

The chief advantage of penicillin which remains undisputed at this time is its almost complete freedom from toxic side effects when given systemically and probably also when it is used locally in moderate concentrations. This agent is also more effective against the staphylococcus and against many other gram positive organisms. These attributes are reflected in the improved general condition of the patients with severe and deep wounds after they are adequately treated with penicillin (4). The limitations of the value of penicillin lie in its failure to control the growth of many local wound contaminants and these contaminants may serve to reduce its effectiveness. It is to be hoped that other antibiotics will be found which are just as innocuous to the host but are more effective against a larger range of organisms.

One point of interest which was brought out in the analysis of the present cases may be mentioned briefly, namely the prognostic significance of high fever and high leucocyte counts in patients with extensive burns. Almost all of the patients whose temperatures were over 104 degrees during the first few days died. Likewise the mortality was high among those in whom leucocyte counts above 15,000 were obtained during the first week after the burns were sustained.

SUMMARY AND CONCLUSIONS

The available data concerning the use of sulfonamide drugs in the patients admitted to the Boston City Hospital from the Cocoanut Grove fire were presented. Chemotherapy, chiefly with sulfadiazine, was given only systemically for the purpose of preventing or controlling infection of the surface burns and of the respiratory tract. The management of the chemotherapy in many of the cases was complicated by the presence of shock and by the inadequate urinary output resulting from this or other causes. Treatment was con-

tinued in what are usually considered to be adequate doses for an average of 11 days. Blood levels were often irregular and were usually lower than those which might be considered desirable. Toxic effects were comparatively infrequent and mild.

It is not possible to evaluate properly the effects of the chemotherapy in the present cases. Infections of deeply burned areas occurred after the first week and were fairly frequent but not severe. Extension beyond the burned area was observed in only 1 case. *Staphylococcus aureus* was obtained quite regularly from the infected area and was usually the predominant organism. Hemolytic streptococci and various gram negative bacilli were also cultured from most of the wounds. The virulence of these organisms and their significance with respect to the wound healing varied considerably but was not possible to assess.

Pulmonary infections were few and usually mild. There was some evidence of infection in the lungs of the fatal cases, but extensive pneumonia was found in only 2 of them. Other patients had protracted respiratory symptoms and physical x-ray signs in the lungs with fever and leucocytosis. It was difficult however to determine to what extent pulmonary infection was responsible for these manifestations, since similar signs and symptoms were noted early in most of the same patients and resulted from the injuries which were sustained. Furthermore, most of these patients also had extensive surface burns and infections of these areas contributed to the fever and the leucocytosis. On the whole it was considered that the chemotherapy was responsible at least in part, for minimizing pulmonary infection and for preventing delayed deaths from pneumonia in many cases.

TABLE III.—SHOCK IN RELATION TO MORTALITY—125 CASES

Degree of shock	Number	Lived	Died	Per cent mortality
None*	57	51	6	10.5
Moderate	35	24	11	31.4
Severe	33	13	20	60.6

*None, no apparent shock, blood pressure above 120, pulse below 100, *Scleritis*, blood pressure below 10, pulse above 100, objective signs of shock present.
Severe, blood pressure below 70, pulse above 100, objective signs of shock present.

ound shock mortality is more than 60 per cent.

It is not within the scope of this paper to discuss the complex and still ill understood phenomena of shock. But there are certain features that have impressed us and are worthy of mention.

1. A clinical picture impossible to differentiate from shock is produced by severe contamination of the peritoneum with the content of colon or distal ileum. There are few cases in which blood loss has not also been a factor. Frequently however the degree of shock exhibited is out of all proportion to blood loss and in most of these cases contamination with colon organisms has been a prominent feature. Burbank has taken hematocrit readings on some of these cases and has found a significant hemoconcentration when blood loss was not marked, near normal hematocrit readings when hemorrhage was combined with contamination in the production of the shock picture, hemodilution when hemorrhage has been the major or sole etiologic factor. We have not, as yet, had sufficient opportunity to confirm these findings but they may be of considerable importance in determining the relative amounts of blood and plasma that are optimum in the treatment of a given patient. A constant observation has been that in those patients in whom contamination is the major or the sole cause for shock, response to replacement therapy is usually slow or non-existent. In these patients the prognosis is very grave.

2. When there is relatively little spillage of colon content, when the perforations are entirely confined to the upper intestinal tract, or the lesions are chiefly or entirely of solid organs, shock is relatively proportionate to blood loss. Unsplinted fractures of major

long bones or disturbances in cardiopulmonary physiology due to associated chest wounds or to blast may disturb this proportionate relationship. It must also be kept in mind that it is possible physiologically to compensate for loss of upwards of a liter of blood from the circulation especially if this loss occurs slowly. The additional loss of relatively small quantities of blood may rapidly induce a state of profound shock. It is well to keep this in mind when considering the replacement of blood loss for the patient faces in every case additional blood loss inevitably associated with major surgery which may prove rapidly fatal if difficulty is encountered in controlling bleeding from a major vessel.

3. Fatal peritonitis has been rare except in those cases in which contamination has not been a major factor in the production of shock. From 1 to 3 hours spent in treating shock is well spent as long as there is continued improvement. The working rule on which we have tried to proceed is as follows: Rapid infusion of whole blood and plasma is begun as soon as possible. An attempt is made to estimate tentatively the probable amounts of blood lost. After an adequate replacement of blood and plasma loss in an hour to an hour and a half's time if there is little or no response to shock therapy there must be active causative factors responsible. In the main there are four such mechanisms most of them amenable to surgery: (a) continued hemorrhage usually concealed; (b) severe fecal contamination of the peritoneum; (c) disturbance of the cardiorespiratory mechanism from thoracic injury; (d) early fulminating anaerobic infection with gas-forming organisms. Blast injury to viscera and massive evisceration less frequently prevent response. If there is no response to shock therapy or if response has begun but is interrupted and the patient's condition begins to deteriorate, operation is begun without delay.

The opinion that massive transfusion of whole blood is essential to the adequate resuscitation of shocked patients cannot be escaped. Plasma has frequently been given in installations first receiving the patient, but is used by us as the initial fluid for replacement

Except in certain desperate cases the wound was closed in layers continuous fine catgut was used in the peritoneum interrupted cotton sutures in the posterior and anterior rectus sheaths. The skin was not closed in any case with perforation of a hollow viscus, as it is our opinion that in most instances wound sepsis originates in the subcutaneous areolar tissue. Coarse mesh vaseline gauze was laid beneath the wire sutures to keep the skin margins apart during the first few postoperative days. A request has been made that these wire sutures be left in place 21 days. No attempt has been made to wall off the operative incision from the exteriorized colon. If there were no hollow viscus perforation the skin margins were approximated with interrupted cotton sutures widely placed. The results have been most satisfactory. There have been no wound dehiscences in the subsequent 100 patients. Cosmetic results have not been optimum but it has not been necessary secondarily to close the superficial wound.

In exploring the peritoneal cavity an attempt is made to retrace the course of the missile. Radical shifts in position of viscera particularly small bowel that may occur subsequent to passage of the missile through the peritoneal cavity should be kept constantly in mind. The blood in the peritoneum is removed by suction and the large clots frequently present both manually and by scooping them out with laparotomy packs. No attempt is made to remove the blood completely because we believe that such a maneuver is manifestly futile and that the blood left acts as an autotransfusion no mat-

tion concealed between the leaves of the mesentery which are likely to be overlooked and are troublesome to close. Particular attention must be paid to the retroperitoneal surfaces of the viscera fused to the posterior parietes. The ascending and descending colons are mobilized and their posterior surfaces inspected if perforation from behind is at all likely. In the same way the duodenum is mobilized by lateral incision and retracted medially to expose its posterior surface. The posterior surface of the stomach is exposed through the avascular gastrocolic omentum or through the transverse mesocolon. The most likely areas for overlooking perforations are thereby exposed. The 2 following cases are illustrative.

CASE 2: An American soldier aged 27 years was admitted 6 hours after sustaining a wound by a mortar fragment that entered the left 10th interspace in the anterior axillary line, the fragments were palpable posteriorly above the crest of the left ilium. The missile had passed through the diaphragm below the pleural reflection, perforated the splenic flexure and entered the retroperitoneal tissues above the left kidney. An anterior perforation was closed after great difficulty was encountered in exposing and mobilizing the splenic flexure. Proximal defunctioning transverse colostomy was performed. The patient died on the 9th postoperative day following a stormy septic course. At autopsy there was found a small perforation on the posterior aspect of the descending colon which had not been closed and drainage from which was responsible for a tremendous phlegmon of the perirenal tissues and the tissues of flank and lower chest.

The extension of this incision through the left rectus and obliques in order better to expose the splenic flexure would have allowed of its complete mobilization and exterioriza-

perforation of the portion of the descending colon between the mesenteric leaves

Whether a small perforation of the colon was missed or whether there was subsequent sloughing of the colonic wall in the area of contusion is not definite. In any case there was an error in judgment. The descending colon should have been exteriorized.

Except for conduction of secretions of liver, kidney and pancreas to the outside no attempt has been made to drain the peritoneal cavity.

That the incidence of involvement of the various viscera is roughly proportionate to their displacement is borne out in Table V. Complex injuries to numerous viscera is the rule, and the contribution to mortality made by each defies statistical analysis.

TABLE V—INCIDENCE OF INVOLVEMENT OF THE VARIOUS ORGANS—130 PATIENTS

Stomach	20	Pancreas	2
Duodenum	6	Adrenal	2
Small intestine	55	Bladder	5
Colon	57	Ureter	1
Rectum	9	Urethra	1
Liver	34	Diaphragm	33
Gall bladder	3	Appendix	1
Spleen	14	Vena cava	3
Kidney	34		

Hollow viscera. Perforation of a hollow viscus was found in 99 cases with a mortality of 38 per cent (Table VI). The tearing action of high explosive fragments tends to produce large lacerations from which spillage of intestinal content is great. The contractile action of the bowel tending to close small perforations minimizes the amount of spillage which in lesions less than 1 centimeter in diameter is usually very slight.

Except for the technical difficulties of approach to the gastric fundus, especially on its posterior surface perforations of the stomach have proved to be relatively benign. Since high gastric lesions are frequently associated with thoracic involvement we have preferred whenever possible to approach them through the chest.

The survival rate of patients with lesions of the duodenum is very low not so much apparently because of factors intrinsic in the duodenum but because of its location near great vessels, the pancreas, the biliary tree,

stomach and colon which tends to make for very complex situation. Duodenal closure even of large lacerations on the posterior no peritonized surface has given little difficulty. None of these closures has subsequently leaked to produce duodenal fistula.

There has always existed among military surgeons firm prejudice against resection of small intestine, founded on previous experience that few survived. Although in complete agreement that simple closure is always to be preferred to resection we have encountered no difficulties with resection per se. We have preferred end-to-end anastomosis chiefly because it has been more rapidly and simply accomplished. With the peritoneum already contaminated closed aseptic anastomosis has seemed an unnecessary refinement, especially since no clamps have been available that met ideal standards of length and narrowness of blades. An open two layer anastomosis has been made in each case, by use of nonabsorbable sutures in the seromuscular layers, and removal of a greater portion of the bowel at the anti-mesenteric border in order to achieve a lumen of greater size. Great care has always been taken that the blood supply of the suture line be adequate. In spite of the fact that all these anastomoses were made in the presence of already established peritonitis none has leaked. Nor has intestinal obstruction developed at the anastomotic site. Patients in whom intestinal resection is necessary will inevitably succumb in higher percentage than those handled by simple closure but it is our impression that this is in very great part due to the greater complexity of the pathology. When several large linear lacerations and transections have occurred in a short segment of bowel it has seemed safer to resect the involved segment and to make a single anastomosis than to attempt plastic closure of these several tears. Linear tears are closed in transverse direction, but great care must be taken that distortion does not make for likely intestinal obstruction later on. Intestinal obstruction varying in degree has been a frequent late complication from plastic peritonitis with volvulus. In most cases the sites of obstruction bearing less relationship to

the areas where perforations were closed or anastomoses made than to the areas where aerosal abrasions have occurred and where the bowel has been handled a great deal during the manipulations of repair.

Colon. Contamination of the peritoneum by colon content is the single most lethal factor producing death in abdominal wounds (Table VI).

TABLE VI.—RELATIONSHIP OF CONTAMINATION OF PERITONEUM TO MORTALITY

	Cases	Dead	Per cent Mortality
Extraperitoneal perforation of hollow viscera	31	0	0
All intraperitoneal perforations	99	38	38
Stomach and small bowel perforations only	41	8	19
Colon perforation	57	30	44

The principle of exteriorization of lacerations of colon is particularly adaptable to the lesions of the colon produced by high explosive and high velocity missiles. Even the smallest perforation of the colon is usually surrounded by an area of ecchymosis which, when observed in the exteriorized loop, invariably undergoes necrosis and sloughs to the very margin of the ecchymotic area. The difficulties of estimation of the extent of this necrosis make simple closure of these lacerations hazardous. In addition exteriorization accomplishes decompression. There are certain situations, however, in which the exteriorization principles are inapplicable or unsatisfactory. These are particularly peculiar to the right colon, large lacerations of which are likely to be accompanied by high mortality because of the liquid character of the colonic content which flows readily into the peritoneal cavity carrying with it a great concentration of organisms which are rapidly disseminated throughout the peritoneum. Exteriorization, with the suturing of ileum to

perforations particularly of the cecum and proximal ascending colon have done very well following the conversion of these wounds into a cecostomy by suturing the colonic wall about a one inch rubber tube and securing it to the deep fascia by several interrupted sutures. When small through and through wounds have been encountered the posterior wound has frequently been closed and the anterior wound converted into a cecostomy in this fashion. The cecostomy is usually removed between the 4th and 6th postoperative days and drainage has ceased a very few days later. By complete mobilization of the right colon and the hepatic flexure exteriorization with the suturing of an adequate spur can usually be accomplished in the distal half of the ascending colon. In those long linear tears, especially in the proximal half of the ascending colon, the most satisfactory answer seems to be resection of the proximal portion to beyond the tear, ileotransverse colostomy (which we prefer to do in end-to-side fashion bringing the proximal hepatic flexure of transverse colon out through a stab wound).

Perforations and lacerations of the remaining colon are exteriorized through a short muscle splitting incision as far away from the primary incision and the wounds produced by the missile as is consistent with the avoidance of tension on the bowel. To this end also attached portions of the colon are liberally mobilized. A spur ideally from 5 to 6 inches in length, is constructed by the simple expedient of turning the bowel toward the center axis of the body suturing the two teniae liberae together with a single running stitch of catgut. Portions of the transverse colon used in making this spur are denuded of their omental attachments. The colostomy thus constructed is opened immediately following operation.

remove them at the initial operation unless they are readily available protruding from the liver surface.

Spleen The gunshot wounds of the spleen have exhibited one striking feature different from the usual experience with closed traumatic rupture of the spleen unless there is a wound of the great vessels near the hilum of the spleen they do not continue to bleed. No satisfactory explanation for this alteration in the usual pattern presents itself. Extensive laceration, even fragmentation of the spleen with free portions herniated into the thorax or free in the peritoneal cavity have been a frequent finding. There is usually considerable free blood in the peritoneal cavity but the spleen itself as encountered at operation is either not bleeding at all or gently oozing. Shock is no more frequent in splenic injuries than in injuries of other abdominal viscera. The following case is typical.

CASE 4. An American soldier aged 24 years was admitted 544 hours after sustaining a wound over the left 11th rib in the anterior axillary line by a mortar fragment. Two units of plasma were given prior to admission. He was not in shock, blood pressure 120/80 pulse 100. The abdomen was boardlike. Stomach contents and urine were negative. At operation the abdomen contained an estimated 2000 cubic centimeters of liquid and clotted blood. There was a tremendous laceration of the lower half of the spleen, with a great deal of surrounding ecchymosis of the ligaments of the spleen but no active bleeding. The diaphragmatic origin was torn below the pleural reflection. Splenectomy was performed and the diaphragm repaired. Except for transient atelectasis of the left lower pulmonary lobe he made an uninterrupted convalescence and was returned to full duty on the 15th postoperative day.

In considering civilian experience in the frequency of secondary hemorrhage following rupture of the spleen we have performed splenectomy for all but the most extremely minor lacerations. The only such case in which it was felt that the slightly fractured spleen could be safely left in had no further difficulty with the spleen during the short period we were able to follow his progress. Splenectomy in cases in which the spleen was the sole abdominal viscus damaged has not resulted in death or severe complication in a single case (Table VII). The transthoracic approach has delighted us in the case with

TABLE VII—MORTALITY FROM SPLENECTOMY
—14 CASES

	Cases	Deaths	Mortality per cent
Transpleuric	9	0	0

Total	14	4	28

*These deaths are due to extensive contamination of peritoneum and pleura by hollow viscus content.

which splenectomy may be performed. If there were no penetration of the pleura, or if the peritoneal pathology were not approachable through the diaphragm the transverse subcostal approach has been used whenever practicable. This series includes 3 patients who have returned to combat duty within 6 weeks after splenectomy.

Kidney ureter and bladder Wounds of the kidney have been seen in 24 patients. In cases with extensive extravasation of blood about the kidney sufficient dissection was carried out to visualize the kidney. As with liver and spleen the renal parenchymal substance has not continued to bleed except for moderate oozing unless the wound were near the hilum involving the major blood supply. Even though there were extensive fractures through the renal substance with portions of the kidney torn completely away and a major calyx involved the treatment has been conservative. Adequate drainage has been established to conduct the urine to the outside. Drainage of urine in these patients has continued for a very long time. Microscopic blood and sterile pyuria have required weeks to disappear. Plastic reconstruction of the kidney by débridement and suture has not seemed indicated. The following case is illustrative of the tremendous powers of healing of the conservatively treated kidney.

CASE 5. A Japanese American soldier aged 27 years sustained a perforating wound from an artillery fragment that passed through the right flank. He was admitted 9 1/2 hours later in severe shock which responded promptly to the administration of 1000 cubic centimeters of plasma and 500 cubic centimeters of whole blood. The missile had torn the lateral 3 centimeters of the right lobe of the liver away almost completely transected the mid-ascending colon and carried away the lower third of the right kidney into the lower major calyx. Neither liver nor kidney was bleeding. The torn colon was exteriorized and the hepatic and renal areas drained through the large débrided posterior wound. Except

for a low grade fever early convalescence was smooth. Urine and bile drained in large amounts through the posterior wound. Six weeks later he was seen at the general hospital in the base still draining bile stained material in small amounts from the small posterior sinus otherwise in excellent general condition. Retrograde pyelograms at this time were normal except for very slight distortion of the inferior major calyx. He stated in a letter almost a year later that he was on limited duty status in a rearward area feeling fine.

Nephrectomy has been performed in 6 instances (25 per cent) in each case because of severe intractable bleeding.

Only 1 lesion of the ureter has been encountered in our personal experience in this case associated with severe damage to the kidney to which the only answer was nephrectomy. We know of no case in which there has been sufficiently slight damage to the ureter to permit of successful plastic repair.

Perforations and lacerations of the bladder have been closed. In certain instances especially when the missile has passed through the floor of the bladder or its anterior wall the dissection in the prevesical spaces has been extensive and the repair difficult. A suprapubic cystostomy tube has been sutured in place for urinary drainage. In many instances indwelling urethral catheter drainage might have sufficed, but the difficulties of maintaining the catheter in place during transportation have made cystostomy the more desirable procedure.

Great vessels. The initial attitude toward the problem of retroperitoneal hematoma was conservative in accordance with the accepted attitude toward the retroperitoneal hematomas of crushing injury of civilian experience. Unless there was continued bleeding the hematoma was left severely alone. An early unfortunate experience (Case 6) which has been repeated in the experience of others has made us more vigorous in exploring these hematomas and in ligating large bleeding vessels, more to avoid the late complication of suppurative thrombophlebitis with fatal septic infarction of lung than to avoid secondary hemorrhage. This has seemed particularly indicated in instances in which the retroperitoneal hematoma communicates through the missile track with the contaminated peri-

toneum and especially when the missile passed through the colon in its course toward the posterior parietes. This attitude has seemed profitable.

CASE 6. An American soldier aged 21 years was admitted 6 hours after fragments from an aerobomb had caused superficial wounds of the right arm and a penetrating wound of the mid-epigastrium. The small missile had passed through the midtransverse colon produced numerous rents and perforations in a segment of ileum a foot from the ileocecal juncture and passed into the retroperitoneal tissues to the left of the midline about 3 centimeters above the origin of the inferior vena cava. The large retroperitoneal hematoma was not increasing in size. There was severe contamination of the peritoneum and the intraperitoneal blood. Resection of a segment of the small bowel with end-to-end anastomosis, the transverse colon exteriorized, the retroperitoneal hematoma not disturbed. For the first 9 days convalescence was satisfactory except for a low grade fever which was first thought to be due to malaria when parasites were found on examination of the blood. At the evacuation hospital he developed an abscess about the posteriorly placed missile lateral to the vertebral bodies which had not been removed. Following the drainage of this abscess he developed severe ileus, high fever, jaundice with marked enlargement of the liver. Death on the 47th postoperative day from a suppurative thrombophlebitis of both femoral veins and inferior vena cava with multiple septic infarcts to lungs and liver.

Exploration of the retroperitoneal tissues might have required ligation of the inferior vena cava, but the removal of the missile and avoidance of the subsequent abscess would probably have saved the patient.

We know of no patient with an aortic wound who has survived to reach the operating table although 2 patients with aortic wounds have succumbed shortly after their admission to our hospital. Lesions of almost every other great vessel have been encountered. Associated with wounds of large vessels is a particular syndrome which it may be well to describe. If the patient has been in severe shock on admission he may make an excellent response to replacement therapy up to a certain point, attaining a blood pressure of perhaps 90 systolic. Or the shock picture may have been slight and response to shock therapy prompt. Immediately however upon the opening of the peritoneum the blood pressure drops to zero with the release of the hydro-

Fig. Case 7. Left thoracoabdominal wound. a, Preoperative vertical roentgenogram of the chest showing stomach herniated through the large rent in the diaphragm, fractured spleen above and medial to the stomach, slight

hemothorax. b, Vertical roentgenogram of the chest 30 hours after thoracotomy showing complete re-expansion of the lung, the stomach reduced, the diaphragm repaired.

static pressure of the collected blood within the peritoneum sustained by the pressure of the abdominal musculature. After ligation of the vessel there is usually prompt recovery from the hypotension. Distention of the abdomen with blood with slow or no response to replacement therapy is a most ominous sign and usually results from a rent in an artery of large caliber. Collected experience has indicated that the great veins may be ligated with impunity including the inferior vena cava up to the level of the renal veins.

THORACOABDOMINAL LESIONS

For purposes of this discussion thoracoabdominal lesions are limited to those in which the missile has passed through both pleura and diaphragm. Combined thoracic and abdominal cases in which there is associ-

ated injury to the chest by one or more other fragments are excluded as are those perforations of the diaphragm beneath the pleural reflection. There were 31 thoracoabdominal injuries in this series, an incidence of 24 per cent. The mortality of this group was 19 per cent, slightly lower than the general mortality of the entire series.

Thoracoabdominal lesions form the most frequent indication for major surgical invasion of the thoracic cavity by definitive thoracotomy. It is beyond the scope of this discussion to consider the indications for definitive thoracotomy in detail. Our present attitude may be summed up as follows. The repair of the diaphragm is much more readily accomplished from above and the repair achieved is likely to be much more secure. If there is a sucking wound or extensive dam-

age to the thoracic wall especially when the thoracic wound is below the 7th interspace affording satisfactory exposure of the diaphragm by extending the incision necessary to débridement of the wound the diaphragm is repaired from above. This approach is especially appropriate if the pathological condition likely to be encountered can be entirely repaired through an extension of the wound in the diaphragm. We have been gratified to find how readily subphrenic organs are approached by the transphrenic route. As has been previously stated the removal of the spleen is much more readily accomplished from above than from below and the same is obviously true of the approach to the gastric cardia and fundus and the entire posterior surface of the stomach. Nephrectomy can be accomplished readily through a low thoracic approach either on the right or the left. The splenic flexure of the colon is readily mobilized and externalized through a subcostal stab wound if perforated. The small intestine may be explored through the left diaphragm down to the distal reaches of the ileum.

Although there has been general agreement about the necessity for closure of the left diaphragm to prevent subsequent herniation, we are of the opinion that it is just as important to close the right diaphragm, if there is a lesion of any size in it, to prevent the drainage of bile into the pleura from the liver wound which is almost invariably associated with lesions of the right diaphragm. Continued flow of bile into the pleura produces an intense chemical pleuritis causing transudation of a great deal of fluid into the pleura requiring aspiration for a very long time. Total empyema is likely to result. The objection that the presence of the liver precludes exploration of the subhepatic areas has not proved a valid deterrent. Nephrectomy has been accomplished through the right diaphragm as readily as through the left. The liver may be retracted to the left, thus exposing the gall bladder the hepatic flexure and proximal transverse colon the duodenum and biliary tree.

The frequency with which the abdominal and the thoracic approach has been selected

TABLE VIII.—THORACO ABDOMINAL WOUND
ROUTE OF APPROACH—31 CASES

Route of approach	Cases	Died	Mort per
Thoracotomy alone	21	2	1
Celiotomy alone	4	2	5
Thoracotomy plus celiotomy	5	3	4
Not operated	1	0	
Total	31	6	1

is shown in Table VIII. In those cases which both thoracotomy and celiotomy may be done we have preferred to do the chest work first in order to restore the pulmonary physiology to as nearly normal as possible before proceeding to the more shockful celiotomy.

The phrenic nerve has been crushed whenever it seemed desirable to achieve phrenic paralysis to quiet the diaphragm and to favor its healing. This fact has seemed particularly indicated when there was an extensive wound of the diaphragm especially in those cases in which the diaphragm was avulsed near its origins for a considerable distance. Phrenic repair has usually been accomplished in two layers by overlapping the leaves of the diaphragm a centimeter and securing the closure with interrupted mattress sutures throughout. Every effort has been made to achieve rapid complete re-expansion of the lung following surgery. The most successful plan has been to institute water trap drainage of the chest through two tubes an upper one in the anterior 2nd interspace another in the posterior axillary line usually in the 7th interspace. The lung has been re-expanded under positive pressure by the anesthetist prior to completing the last sutures in the thoracotomy closure. The tubes have been removed after they have ceased to function when the lung has come out against them usually in 48 hours. In many instances the chest has remained completely dry (Case 7) although frequently from 1 to 4 daily aspirations have been necessary. Aspirations are continued until less than 50 cubic centimeters are obtained.

CASE 7. An American soldier aged 21 years was admitted 4½ hours after sustaining wounds of both chests from artillery fire not in shock with blood pressure of 130/70 pulse of 120. The missile had entered the right posterior chest over the 10th rib

just medial to the posterior axillary line and exited through the left chest fracturing the 8th and 9th ribs. This wound was sucking markedly. There was a small amount of blood in the gastric washings. The x ray film (Fig. 1a) showed the stomach herniated through the left diaphragm into the left thorax. Thoracotomy was performed by excising an additional length of the 9th rib. The fractured spleen was herniated with the intact stomach through a large rent in the diaphragm and there were several free fragments of spleen, comprising about half the spleen in the pleural cavity. The remaining spleen was not actively bleeding. Splenectomy was performed, reduction of the herniated stomach and repair of the diaphragm with two rows of interrupted cotton sutures. After the pleural toilet was completed the lung expanded readily with positive pressure except for the lower border of the lower lobe where there was a short laceration which was not bleeding. The chest was closed and a tube left in the 6th interspace in the posterior axillary line, another in the 2nd interspace anteriorly, both connected with water trap drainage. Debridement of the wound entrance with closure of the deep muscles over the small defect in the left pleura. The patient received 1 unit of plasma and 500 cubic centimeters of blood during the 70 minute procedure. Coagulability was smooth. Patient was sitting on the side of the bed eating a full diet on the 2nd post-operative day. X ray films of the chest 36 hours after operation show complete expansion of lung (Fig. 1b).

CHEMOTHERAPY

Enthusiasm for chemotherapeutics in the treatment of peritonitis in civilian practice has not been borne out by our experience in war surgery. The practice of administering sulfadiazine in tablet form as soon as possible after wounding is completely contraindicated in the man with a possible abdominal wound. Peristalsis and absorption cease abruptly at the time of wounding. The tablets frequently plug the gastric tube and are often recovered from the free peritoneal cavity. In an initial group of 18 cases we adopted a regimen of intensive sulfadiazine therapy giving 10 grams intravenously preoperatively instilling 10 to 15 grams of sulfanilamide crystals into the peritoneal cavity and continuing with 5 grams of sulfadiazine every 3 hours following operation. There remained cases of overwhelming contamination which were not apparently affected by this intensive therapy. We were also encountering a distressing number of renal failures and it was hard to be certain that acetylation of the sulfadiazine

with the deposition of crystals in the kidney was not a factor in producing this condition.

In April 1944, penicillin became available in sufficiently large amounts to warrant its use in cases of this type. Since that time we have used no sulfa drug. One hundred thousand units of penicillin were given intravenously preoperatively to every patient with likely intraperitoneal perforation of colon 25,000 units otherwise routinely. In those patients with severe contamination or established peritonitis, 100,000 units dissolved in 200 cubic centimeters of saline have been instilled into the peritoneal cavity through a catheter directed to the major areas of contamination just prior to finishing snug closure of the peritoneum. In all patients, regardless of the presence or absence of hollow viscus perforation 25,000 units have been routinely administered every 3 hours until the indication has no longer existed, frequently throughout the patient's 10 day stay in our unit. We have observed no difference in the patients who have received penicillin except that the associated soft tissue wounds have appeared cleaner. In cases of the same type patients have continued to succumb to their contamination. Renal failure has occurred with the same frequency. We suspect that if neither drug was available the result would be the same.

It should be pointed out in this connection that these views are not thoroughly concurred in by many surgeons working with these same types of cases, particularly because of the known inefficacy of penicillin in combatting the growth of *Escherichia coli* and its allied organisms. There is sufficient indication that the *Escherichia coli* is not the lethal organism in peritonitis, but rather that the clostridial and the anaerobic streptococci are. Since both of the latter are effectively combatted by penicillin, we have felt the objection to its sole use invalid. Clinical impression would seem to substantiate this view.

POSTOPERATIVE MANAGEMENT

If a shock state exists at the completion of surgery, the patient remains on the same litter on which he was operated upon in the deep

Trendelenburg position during the continuance of resuscitation. When all blood lost seems adequately replaced plasma infusion is continued slowly (40 drops per minute). Oxygen at 8 liters a minute is given usually by means of a soft intrapharyngeal catheter. Blood pressure and pulse readings are recorded by the nursing staff at half hourly intervals until stabilized at normal for a 2 hour period when the treatment is stopped.

Nasogastric suction is instituted through an indwelling gastric catheter of No. 18 F caliber when available. This suction is continued until audible peristalsis has been resumed usually about the 4th or 5th postoperative day even when there has been extensive contamination. It was early recognized that these patients stand the administration of electrolytic solutions poorly, tending to develop pulmonary edema. The following case is illustrative.

CASE 8. An American soldier aged 20 years was admitted 2 hours after sustaining a penetrating wound of the left flank and abdomen by small arms fire in profound shock, blood pressure and pulse unobtainable. Response to infusion of two units of plasma and 1500 cubic centimeters of blood was slow and the blood pressure 3 hours later was 70/40 although the pulse was 88. Operation was undertaken immediately. There was an estimated 3000 cubic centimeters of blood in the peritoneum only slightly contaminated. The gallbladder had entered through the leaves of the mesentery of the descending colon at about its midpoint perforating it tangentially extraperitoneally passed through the upper jejunum and entered the retroperitoneal tissues. There was a long laceration of the left common iliac vein which was bleeding briskly. The vein was doubly ligated above and below the rent. The jejunal perforation was closed and the descending colon exteriorized. Although 3000 cubic centimeters of blood was given during the procedure he was in severe shock at its close but over the next 12 hours blood pressure and pulse were stabilized within normal range of values. There followed 3 days of very satisfactory convalescence with slight fever although the pulse remained above 120 and there was moderate oliguria; the urinary output reaching 500 cubic centimeters on the second day. On the third day an hour after the completion of the infusion of 1000 cubic centimeters of dextrose-saline and 1 unit of plasma at 40 drops a minute over a 3½ hour period, he developed sudden severe dyspnea, cyanosis, diffuse moist rales over both lung fields and rapid thready pulse. Because of the sudden character of the onset the known injury to a great vein and the absence of dilatation of peripheral and neck

veins a sublethal pulmonary embolus was suspected. After temporary improvement, 13 hours later he developed fulminating pulmonary edema and died. The sole findings at autopsy were wet, edematous lungs and a markedly flabby edematous heart. There were no anterior clots in any of the great veins. The peritoneum smooth and glistening throughout and the jejunal perforation well closed.

This case is illustrative of the caution which must attend the administration of fluids to patients who have been in marked shock severe cardiovascular instability.

Departure was therefore made from the usual regimen of replacing fluid loss in the presence of gastric siphonage. No fluids are given until a 24 hour interval has elapsed after the recovery from shock and fluids are then begun cautiously. A drip apparatus introduced into the system and the administration rate kept at 40 drops a minute. One unit of plasma is added to each thousand cubic centimeters of dextrose solution to aid maintaining plasma proteins. After twenty-four hours hematocrit, plasma protein, hemoglobin and red blood cell determinations are made and the relative amounts of blood plasma given are guided by the presence of hemoconcentration or hemoconcentration. Careful records are kept of the urinary output so as to provide a further guide in the administration of fluids.

Pulmonary complications are particularly troublesome in this type of case and every precaution must be taken to prevent the accumulation of bronchial secretions, pulmonary atelectasis. The active measures taken to this end are:

1. Careful suction toilet of the tracheo-bronchial tree at the close of anesthesia with bronchoscopic suction if indicated.

2. Frequent turning of the patient manual support of the abdomen with insistence that he cough. The nursing and enlisted personnel on the wards have become particularly proficient in this maneuver.

3. Avoidance of excessive sedation depressing the cough reflex.

4. Frequent inhalation of pure carbon dioxide inducing hyperpnea and cough.

5. Early recognition of atelectasis by frequent examination of the patient.

thrombophlebitis likely. Every possible measure must be taken to prevent this complication, especially early and frequent change of position and as early mobilization as possible. We have recognized thrombophlebitis in only 2 patients of this group, and none has developed massive pulmonary embolus.

As soon as peristalsis has begun again and the duodenal tube is removed the patient is placed on a general diet. During the early postoperative period intravenous vitamin supplement is routinely administered ascorbic acid in 300 milligrams daily dose the B complex, and vitamin K. This therapy is continued by mouth as soon as it can be ingested. In spite of these measures there is usually visibly rapid nutritional depletion of the patient who may already have suffered considerable depletion resulting from long weeks in combat.

Early experience in the African campaign demonstrated that patients who have undergone major surgical procedures or who are suffering from peritonitis do not stand transportation within the first few days of operation. Ten days has been set as the minimum ideal time for evacuation. At the end of this time many are afebrile, eating a full diet, and have begun to sit in a chair beside their cots. Under the stress of a rapidly moving front, and occasionally when evacuation of the hospital has been forced by enemy shell fire it has been necessary to evacuate patients earlier. The average time for evacuation of this entire series was 10 to 7 days.

DISCUSSION

This opportunity to observe the pathology and altered physiology produced by the rapid flooding of the peritoneal cavity with the content of colon or terminal ileum has brought to our attention a pattern of events so uniform in their fatal characteristics that we prefer to speak of it as the syndrome of overwhelming contamination. Typically the patient is admitted in a shock state which responds slowly and incompletely to replacement therapy. When the peritoneal cavity is opened there is a large amount of foul smelling fecal stained blood. The peritoneum is stained a purplish brown has a grayish cast

is lustreless and there are areas of intense hyperemia particularly over loops of small intestine. Fibrin deposition has not as yet begun. The patient usually goes into deep shock during the operation from which his recovery is slow and frequently never complete. In spite of the continuance of plasma administration, he develops an intense hemoconcentration with evidences of markedly slowed circulation of the peripheral capillaries. The blood pressure gradually falls the pulse rate rises, and death occurs in the first 24 hours. In those patients who survive for a longer period reaching the 3rd or 4th day there is invariably pulmonary edema. Large amounts of frothy fluid well into the trachea which they are too weak to cough up and which it is difficult to remove sufficiently well by intratracheal suction. Fever is rarely high before death occurs between the 3rd and 5th postoperative days. At autopsy one is especially impressed with the fact that the peritonitis has continued to improve. In fact in certain cases there is the very minimal evidence of peritonitis—a few areas of peritoneum that have lost their sheen a few flecks of fibrin. Unless there is continued leakage into the peritoneum a true fibrinopurulent peritonitis is not seen. In certain of these cases peristalsis may have been re-established prior to death diet tolerated and the colostomy may have begun to function. The major gross pathology is in lungs and heart. The lungs are intensely wet, water logged the bronchi full of thin frothy fluid. Certain areas of atelectasis and pneumonitis may be present but the picture is chiefly one of edema rather than pneumonia. The heart is invariably very edematous chiefly in the subepicardial layers, the myocardium pale and flabby the entire heart dilated especially the right ventricle.

There occur certain instances in which there is massive spillage of colon content in which there is not this peritoneal staining. Usually the feces is solid in these patients. There is usually intense hyperemia of the peritoneum and a puriform exudate with little odor. These patients live. The others die. Although it is undoubtedly important it would seem that the picture bears little

abdominal cases than in other severe injuries. The one most striking feature seems to be that almost all have been for long periods in extreme hypotension states. They have therefore received large amounts of blood in the resuscitation. Only a few have shown clinical evidences of transfusion reaction and in these there has been extensive hemolysis in plasma and urine typical of transfusion reaction. Detailed studies are now being made on the problem. We feel that it has little relationship to the administration of blood and prefer to call it "shock kidney."

Further reduction in the mortality of the abdominal wounds of warfare depends chiefly upon the solution of these two problems.

SUMMARY

1 Experience in the initial surgical care of 130 war wounds of the abdomen is presented. The mortality in our hands was 23.4 per cent.

2 Diagnosis is chiefly a problem of reconstructing the course of the missile. The usual signs of peritoneal irritation are reliable. The presence of peristalsis rules out intraperitoneal perforation of hollow viscus.

3 It is profitable to operate on every patient with an abdominal wound regardless of time lapse or risk.

4 Exploratory celiotomy is rarely necessary.

5 The degree of shock on admission is the most reliable prognostic sign.

6 Severe fecal contamination of the peritoneum produces a clinical picture impossible to differentiate from shock. These patients respond slowly or not at all to replacement therapy.

7 Shock treatment is continued as long as improvement continues. It is rarely profitable to give more than 1500 cubic centimeters of blood prior to operation.

8 Ether-oxygen anesthesia by closed ab-

sorption endotracheal technique is the anesthetic of choice.

9 Although the function of the surgeon is primarily to save life it is rarely necessary to adopt compromise procedures.

10 Resection of small bowel is preferable to multiple closures within a short segment which may distort and lead to obstruction.

11 Exterionization of the wounded colon is the safest procedure. Perforation of the colon remains the single most lethal factor in any series of abdominal wounds.

12 Adequate drainage of liver wounds is essential. Liver packs are rarely if ever, necessary and are productive of complications.

13 Solid viscera including the spleen, do not continue to bleed significantly from their parenchyma.

14. Intractable bleeding from a hilar vessel and division of the ureter form the sole indications for removing the wounded kidney.

15 Closure of the diaphragm is as important on the right as on the left.

16 Penicillin is no more effective than the sulfanilamides in preventing death from severe contamination of the peritoneum.

17 Intravenous administration of isotonic electrolytic solutions postoperatively is poorly tolerated by the patient recovering from a severe shock state or combatting peritonitis.

18 Pulmonary complications must be anticipated and vigorously treated.

19 Overwhelming contamination of the peritoneum and renal insufficiency remain the two problems the solution of which must precede marked further reduction of mortality from abdominal wounds.

THE EFFECTS OF PEDICLE JEJUNAL TRANSPLANTS IN THE STOMACH ON MANN-WILLIAMSON DOGS

HARRY C. SALTZSTEIN M.D. F.A.C.S. and IRVIN J. KURTZ, M.D., Detroit, Michigan

ANDRUS Lord and Stefko reported that when pedicle grafts of the jejunum were transplanted into the stomach wall of dogs a reduction in gastric acidity ensued. In such animals following histamine injections there was a reversal or considerable diminution in the expected rise in acidity. These results were obtained particularly with jejunal transplants, although a duodenal flap caused similar changes but in a lesser degree. No effects were produced with ileal or colonic segments.

They then produced gastroduodenal ulcers by the injections of histamine-beeswax mixture after the method of Varco. Jejunal transplants into the stomach had a salutary effect on these ulcers. In 3 dogs previously prepared with grafts, no ulcers formed after histamine-beeswax injections.

Applied to humans (3) jejunal flap transplants were done in 4 peptic ulcer cases. Hyperacidity was reduced in 3 of these patients and clinical improvement without change in acidity was noted in the fourth patient.

In ulcers produced by the histamine-beeswax method the beeswax is imbedded in the subcutaneous tissues. The secretagogue effect of the histamine causes continuous gastric hypersecretion. Chronic ulcers form in the stomach or duodenum in 100 per cent of cases.

Another standard method of producing chronic duodenal ulcers in dogs is the Mann-Williamson operation (6). In this procedure the stomach is made to empty into the jejunum and the alkaline duodenal bile and pancreatic juices are diverted into the terminal ileum. Acid gastric juice thus spurts constantly against an area of jejunum unprotected by its normal alkaline juices.

From the Experimental Surgical Laboratory, Harper Hospital, Detroit, Michigan. Aided by grant from the Macdonald Fund. Prepared for presentation before meeting of Central Surgical Society in February, 1945, cancelled.

We have done the Mann-Williamson operation on 28 control dogs whose diet consisted of left overs from the hospital kitchen. In all cases (100%) jejunal ulcers were demonstrated at necropsy. The survival time averaged 71 days. The minimal time from operation to expiration was 13 days, and the maximum 135 days (7).

We wish to report our observations on 6 Mann-Williamson dogs in which jejunal pedicle graft transplants were done (Table I). These operations were done in one or two stages.

TECHNIQUE

Intravenous nembutal anesthesia was used. The abdomen was opened through a midline incision. A segment of jejunum $1\frac{1}{2}$ to 2 inches long and 3 to 4 inches from the ligament of Treitz was isolated and divided. Meticulous attention was given to the integrity and adequacy of the attached mesenteric blood supply.

The posterior wall of the stomach was then delivered through a rent in an avascular portion of the mesocolon and serosal sutures were placed joining the prepared section of jejunum to the stomach. The cylinder of jejunum was then incised at its antimesenteric border and the edges were trimmed, thus forming a flap. A gastric window was fashioned to accommodate the jejunal patch, and the pedicle graft was secured in place with two rows of sutures usually silk throughout.

When the jejunal transplant was done as a first stage or preliminary procedure, the continuity of the jejunum was then re-established either with a side-to-side or end-to-end anastomosis, and the abdomen was closed.

The second stage consisted of the typical Mann-Williamson operation. The stomach was divided at the pylorus, and the duodenal end was inverted and closed. The jejunum was sectioned about 1 inch distal to the previous anastomotic site. The open pyloric end of the

stomach was anastomosed into the distal jejunal segment. The proximal jejunum was then joined to the terminal ileum (8 to 10 inches from the ileocecal junction) thereby providing the surgical duodenal drainage. Anastomoses were generally side-to-side or end-to-side occasionally end-to-end. Silk was used throughout. The two stage operation was done in 3 dogs. The interval between the 2 operations was 25, 29 and 47 days, respectively.

Because of the technical difficulties of adhesions encountered when the abdomen was

entered a second time the two procedures were combined in one operation in 4 animals. When thus performed the pedicle graft was fashioned into the posterior stomach wall first. Then the stomach was divided at the pylorus and the duodenum was closed. The open ends of the jejunum where the transplant has been removed were then used for the Mann-Williamson anastomoses, the distal one for the pyloric end of the stomach, the proximal one joined to the terminal ileum.

RESULTS

In Table I it will be noted that despite pedicle jejunal graft transplants all dogs except one developed jejunal ulcers. The one exception dog No 208 developed an ulcer of the jejunal pedicle transplant (Fig 2). The ulcers were identical with the ones we have been accustomed to seeing with control Mann-Williamson dogs. The photographs show this clearly. There are superficial ulcers penetrating into the muscularis, and ulcers which have perforated completely. They form in the identical location— $\frac{1}{2}$ centimeter beyond the pylorojejunal anastomosis or slightly distal to this point as they did in our

controls. Two of the photographs show that the blood supply at the base of the transplant (and also in the vascular pedicle) is intact.

The survival time average, 70 days was about the same 71 days as in our control animals.¹

CONCLUSION

The healing and prophylactic effects attributed to the jejunal flap in dogs with histamine induced ulcers were not evident in 6 dogs with

The seventh experiment was not completed at the time this paper was submitted. It was one stage operation done on December 30, 1944. The dog was sacrificed August 7, 1945, (8 months later) at which time there was 25 per cent weight loss and the dog was almost moribund. Autopsy showed large well nourished pedicle graft. The jejunum showed no ulceration (Fig. 8). Since this was one of the larger jejunal grafts, further work will be done using even larger transplants.

the Mann-Williamson ulcers. Ulcers formed eroded and perforated in spite of viable grafts. The seventh dog was sacrificed 8 months after operation. There was no ulcer present in this animal.

NOTE: Since this work has been completed, two articles have appeared testing the value of pedicled jejunal transplants on gastric acidity. Kolouch, Dubuc and Wangenstein reported that the histamine effect was not reversed in pedicle transplant dogs, as Andrus and associates had found. Also, when daily intramuscular injections of histamine in beeswax were given, the jejunal transplant showed reduced resistance and invariably ulcerated in the presence of this induced continuous gastric hypersecretion. Using Heidenhain's pouch dogs, the pedicle graft caused slight but inconstant depression of gastric acidity, but it did not regularly inhibit gastric secretion from the pouch and gastric juice from such pouches as irritating as normal gastric juice when delayed out exteriorized duodenal mucosa.

Crossman, Dutton, and Ivy also tested the gastric acid secretory response to histamine stimulation in pedicle jejunal grafts. They found no significant change.

PRIMARY CARCINOMA OF THE FALLOPIAN TUBES

KARL A. LOFGREN M D and MALCOLM B DOCKERTY M D Rochester Minnesota

PRIMARY carcinoma of the fallopian tubes is a rare disease. Its infrequent occurrence is especially evident when it is compared with the rather frequent incidence of malignant neoplasia in the uterus and the ovaries which, with the tubes originate from the muellerian duct. Moreover the clinical manifestations of tubal carcinoma are so protean that the internist rarely arrives at a correct diagnosis even when the process is far advanced. At the operating table the surgeon often is confused by the appearance of hydrosalpinx and may fail to realize that a distended condition of the fallopian tubes may obtain on a malignant basis. He consequently may be led to carry out an inadequate sacrifice of tissues. Even the pathologist has difficulty in differentiating from carcinoma of the tubes such divergent lesions as adenomyosis and tuberculous salpingitis. In consideration of the aforementioned facts and the added knowledge that primary tubal carcinoma carries an extremely bad prognosis attempts made along the line of establishing criteria for early diagnosis of the condition would seem to fulfil a worthy purpose. Our contribution consists of a review of the literature and the clinical and pathologic analysis of 16 cases of primary carcinoma of the fallopian tubes seen and studied at the Mayo Clinic in the past 40 years.

HISTORICAL DATA

Orthmann in 1888 described what is now generally accepted as the first authentic case of primary carcinoma of the fallopian tube. Although he collected, reviewed and accepted 13 earlier examples from the literature examination of these cases in the light of more recent knowledge leads to the belief that they were instances of metastatic rather than of

primary involvement. Doran(6) in 1888 recorded the second well established example and expressed the opinion that the growth had its origin in a benign tubal polyp. Kaltenbach in 1889 reported the third case and described the papillary and alveolar pictures which are now almost standard in descriptions of the microscopic appearance of the lesions. Rouzier in 1893 and Tuffier in 1894 furnished the fourth and fifth cases respectively according to Holland. In 1901 Le Count was able to review 21 cases from the literature and to point out the frequent association of hyperplastic salpingitis as a possible etiologic factor. In 1911 von Franqué emphasized the frequent occurrence of tuberculous salpingitis as a precursor of tubal carcinoma and this was again stressed by L. Esperance in 1917 in a review of 49 cases of primary carcinoma of the fallopian tube accumulated from the literature. L. Esperance described a case of epidermoid carcinoma of tubal origin a type of lesion first recorded for this location in 1916 by Barrett. The number of authentic examples of primary tubal carcinoma had reached the hundred mark in 1910 when Doran(7) supplemented his original report. Along with Orthmann and Vest this investigator pointed out the difficulties of diagnosis, the tendency toward early dissemination and the gloomy prognosis. Vest stated that surgical operation offered a little less than a 4 per cent chance of cure. With stimulated interest in the subject, reports of individual cases of this rare disease found their way into the literature so that Kahn and Norris in 1934 were able to collect published data on 323 cases. This number was increased to 427 when Mullins and Mosteller reviewed the subject in 1942. With the cases published in the past 2 years added to those of the present series the accumulation has now reached 450.

MATERIAL AND METHODS

The investigation of the material for the present study began with a search of the files of the Mayo Clinic for cases in which car-

From the Mayo Foundation, and the Division of Surgical Pathology, M. Y. Clinic.

Abstract of thesis submitted by Dr. Lofgren to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirement for the degree of M. S. in Surgery.

Since this paper was written Dr. Lofgren has entered the armed services and is now Lieutenant in the Medical Corps of the United States Army.

cinoma involved principally the fallopian tube or tubes. Forty two such cases had been encountered over a 34 year period from 1910 to 1943 inclusive. The pathologic specimens, removed surgically or at necropsy, were all available and were inspected grossly to exclude those cases in which the tubal involvement was obviously metastatic in nature. Excluded also were those cases in which massive involvement of the pelvic viscera made it unlikely that the matter of primary tubal origin of the malignant growth could be decided with certainty. Selected for further investigation were specimens in which the involvement was strictly limited to the tubes and a second doubtful group in which although concomitant involvement of the uterus and ovaries was present, it appeared to be grossly of a metastatic nature. No cases in which the tubal mucosa remained intact were accepted for study. In every instance multiple blocks of tissue were removed from involved and uninvolved portions of the tube and from the associated ovarian and uterine lesions when the latter were present. These blocks were placed in a fresh 10 per cent solution of formaldehyde (3.7 per cent commercial formalin) sectioned at 7 microns with a freezing microtome and stained routinely with hematoxylin and eosin. In cases in which mucus seemed to be present in sections stained by the aforementioned method sections cut from paraffin blocks were stained with mucicarmine. The microscopic finding of psammoma bodies and of papillary mucous carcinoma, when tubal and ovarian lesions coexisted was considered as being fair evidence that the primary lesion was in the ovary. Similarly the finding of adenocarcinomatous zones in a lesion involving the uterus and the tube or tubes was conceded as indicating a uterine origin. Discarded along with these samples after careful microscopic study were 2 specimens of tubal tuberculosis with epithelial hyperplasia. A residue of 16 cases of true primary tubal carcinoma remained to serve as a basis for this report.

CLINICAL AND PATHOLOGIC DATA

Incidence. Sixteen primary carcinomas of the fallopian tube were found in approxi-

mately 10 000 patients suffering from primary malignant lesions of the female generative tract an incidence of 0.16 per cent. Stuebler and Brandess in a comparable analysis found an incidence of 0.45 per cent. Anspach found only 1 instance of primary tubal carcinoma among 19 439 patients admitted to the gynecologic service at the University Hospital in Philadelphia.

Age. The average age of our 16 patients was 50.9 years with extremes of 34 and 65 years. Nine of the 16 patients had passed the menopause. In the literature 18 and 80 years represent the extremes of age for patients suffering from the effects of primary carcinoma of the fallopian tube. According to Wechsler 66 per cent of the patients affected are between the ages of 45 and 55 years almost a decade prior to the peak incidence seen in cases of uterine (fundal) carcinomas.

Symptoms. The commonest complaint was vaginal discharge. This was present in 10 of the 16 cases and in 7 it was the principal symptom. Duration had varied from 3 days to 1 year with an average of about 5 months. In postmenopausal patients the discharge was constant and in younger women it was described as being intermenstrual. The character of the discharge varied from leucorrhea to frank bleeding. In only 1 instance was it described as malodorous. In 1 case the discharge had continued without interruption following curettage of atrophic endometrium. Throughout the literature this phenomenon namely persistence of discharge following curettage has been repeatedly emphasized as being characteristic of the vaginal discharge associated with tubal carcinoma as opposed to other lesions causing this symptom (22-30). According to Anspach other characteristics of this symptom include the occurrence of the discharge in sudden gushes accompanied by paroxysms of cramp-like pain a phenomenon to which the term *hydrops tobæ profuens* has been applied.

Pain in the lower portion of the abdomen usually on the side of tubal involvement was the second commonest symptom and it was a major complaint in 8 of the 16 cases. In 1 case constant, dull pain had been present for 15 years. It probably was related to the

chronic pelvic inflammatory condition associated with the tubal carcinoma. In the other 7 cases the pain was usually of shorter duration than the vaginal discharge. The pain was crampy and intermittent in character in 6 of these 7 cases and seemed to be related pathologically to distention of the affected tube produced by the expansion of the malignant growth. In 1 case however the pain took the form of an acquired dysmenorrhea and it was accordingly impossible to correlate etiologically with the pathologic lesion in the fallopian tubes. Pain was a prominent symptom in 53 per cent of the cases of tubal carcinoma analyzed by Doran. Fullerton felt that it was produced by stretching of the muscular coats of the tubal wall.

Three patients complained of lower abdominal swelling which had been present for from 3 weeks to 2 years. In 1 of these cases the swelling appeared to obtain on the basis of the size of the carcinoma *per se* whereas in the other 2 the presence of associated hematosalpinx augmented the bulk of the tubal neoplasm. In the literature this symptom is listed along with vaginal discharge and pelvic pain as completing a triad frequently based on the presence of primary tubal carcinoma.

Symptoms of a miscellaneous nature commonly found among women suffering from various gynecologic lesions included backache a bearing-down feeling constipation dysuria frequency menometrorrhagia and so forth. In our series they did not occur in any combination or in any sequence which could be interpreted as being diagnostic of the underlying tubal disorder.

Physical findings. In 14 of the 16 cases masses were demonstrated on pelvic examination. These were described as varying from 4 to 15 centimeters in average diameter and were generally nontender. The right side was given as the location in 5 instances the left in 1 and in 1 bilateral masses were palpated. An anterior and a posterior relation to the uterus were described in 2 cases each and in the remainder the lesion was either too large or too ill defined for more accurate localization than that denoted by the term pelvic. In about half of the cases the masses seemed movable whereas fixation of

varying degrees characterized the rest of the tumors. One of the patients was suffering from the effects of an abdominal sinus tract which had developed after an operation elsewhere for pelvic inflammatory disease. Carcinomatous tissue curetted from this sinus tract suggested the diagnosis of primary tubal carcinoma but in none of the other cases was the true nature of the lesion suspected clinically as one would expect from lack of specificity of symptoms and results of examination. In the literature although primary tubal carcinoma is productive of palpable pelvic masses the diagnosis is established preoperatively only through the medium of unusual circumstances such as that just cited. Falk in 1898 established it in 1 case by examination of material aspirated through the cul de sac by means of a needle and syringe. Martzloff in 1940 duplicated the feat by finding atrophic endometrium in a woman who complained of a watery vaginal discharge and who had a right adnexal mass which was demonstrated on pelvic examination.

Surgical findings. The gross appearance of primary tubal carcinoma as seen at the time of surgical exploration was often deceptive. In 6 instances the involved tubes were distended particularly at their fimbriated extremities the condition resembled hydrosalpinx pyosalpinx or hematosalpinx. In these 6 cases no adhesions and no carcinomatous implants were present and the true nature of the lesion was not suspected until the tubes were opened in the laboratory. In 4 cases unilateral or bilateral tumor masses had produced adhesions to neighboring structures such as the uterus the sigmoid the cecum or loops of small intestine. In this group there was a marked resemblance to chronic tubo-ovarian inflammatory disease. In the remaining 6 cases the correct diagnosis was anticipated by the finding of adhesions near the growth plus malignant appearing implants on the surface of the corresponding or the contralateral ovary the posterior surface of the uterus the sigmoid or the cecum. In 2 cases the corresponding broad ligament was infiltrated by carcinomatous tissue. One of the patients had associated ascites which appeared to obtain on a malignant basis. The operative

ovarian implant is indicated.

procedure in these 16 cases was hysterectomy with bilateral salpingo-oophorectomy because of the laboratory diagnosis of tubal carcinoma from fresh tissue. In 2 cases dissection of pelvic lymph nodes also was performed. In 2 cases an attempt was made to remove local peritoneal implants but in only 10 cases was the surgeon at all satisfied that he had eradicated the gross evidences of malignant disease.

Pathologic data. Gross appearance. The right fallopian tube was involved in 8 and the left in 7 cases. The incidence of bilateral involvement was 6 per cent, about a quarter that reported in the literature. The size of the lesions varied from 20 by 15 by 10 centi-

meters to 2 centimeters in average diameter. The size of several of the larger lesions seemed to be augmented by the presence of associated hydrosalpinx or hematosalpinx. As indicated in the foregoing 6 of the lesions were encapsulated whereas the remainder were adherent and frequently demonstrated carcinomatous extension in the form of superficial nodules or distant implants. For the most part the growths seemed to involve the outer or more distensible portions of the tube (Figs. 1 and 2). From 1 of the carcinomas a sinus tract lined by malignant tissue had extended from the right fallopian tube to the anterior abdominal wall. Hematosalpinx was found in 3 hydro-

Fig 3. Primary squamous cell epithelioma, grade 3 of the left fallopian tube. The pathologic mitosis (upper left) the absence of pearly bodies, and the general variability in the size of the cells and of the nuclear staining are indicative of rapid growth. Hematoxylin and eosin stain $\times 251$

Fig 4. Primary papillary adenocarcinoma, grade 1 of the right fallopian tube. Papillary projections are delicate and covered by one or two layers of hyperchromatic tumor cells which however appear to be fairly well differentiated. The psammoma body (dark) is a rather unusual finding. Hematoxylin and eosin stain $\times 63$

salpinx in 2 and pyosalpinx in 2 of the involved tubes. In the remainder the tubal distention obtained on the basis of proliferating carcinomatous tissue per se. Grossly this tissue appeared to be papillary in 8 of the tumors whereas in the remainder no particular gross architecture was manifest, the tissue being grayish red soft friable and frequently necrotic. In 6 tumors a superficial attachment to the capsule was noted but in the remainder there was evidence of invasion with peritoneal involvement in 8. Uninvolved portions of the tubes appeared grossly to be thickened and inflamed. Subacute and chronic salpingitis affected the contralateral fallopian tube in 10 of the cases exclusive of the one in which the malignant lesion was bilateral. Watkins and Wilson remarked on the close resemblance between tubal carcinomatous and inflammatory lesions. In both the ostium of the tube tends to become occluded or attached to the homolateral ovary with the formation of a tubo-inflammatory mass. In this way spillage of carcinoma cells may be averted until the growths are large (23).

Associated ovarian pathologic lesions consisted of malignant implants in 2 cases, dermoid cyst in 1 case, simple cysts in 2 cases and perioophoritis usually of the homolateral ovary in 6. The uterus harbored peritoneal implants in 3 cases and in 5 were the seat of multiple fibromyomas. In this series no

metastasis to the endometrium was encountered as reported by Thaler, Bower and Clark, Ries, Mueller and von Franqué.

Microscopic features. The microscopic features found in our cases of primary tubal carcinoma differed in no major respects from those described in standard treatises on the subject (6, 7, 12, 15, 16) and will be described only briefly. The essential composition was that of epithelial cells which were short, columnar to cuboid and devoid of cilia. Nuclei were large and hyperchromatic with prominent nucleoli and mitotic figures whose frequency in general paralleled the degree of dedifferentiation of the tumor cells. According to the classification and method of grading devised by Broders one of the tumors was epidermoid carcinoma grade 3 (Fig 3) whereas the remaining 16 tumors (1 bilateral) were classified as adenocarcinomas. The degrees of dedifferentiation in this adenocarcinoma group were such that in 1 tumor it was graded 1, in 10 graded 2 and in 3 graded 3. The remaining 2 tumors were of a grade 4 order of malignancy. The lesions of grade 1 and grade 2 malignancy were practically all papillary with single or double layers of fairly well differentiated tumor cells investing the surfaces of delicate connective tissue cores which provided coarse finger-like or delicate filamentous supporting trellises (Fig 4). These lower grade neoplasms did not appear to be as

Fig. 5. Alveolar adenocarcinoma, grade 3, of the fallopian tube showing cellular anaplasia, poor alveolar formation and invasion of the muscularis. A foreign body giant cell is present in large rim. Hematoxylin and eosin $\times 45$.

Fig. 6. Mucocarcinoma, grade 4, of the right fallopian tube. Cellular atypia, nuclear hyperchromatism, many mitotic figures indicate anaplasia. A poorly formed acina space just above and to right of center is all that indicates glandular origin. Hematoxylin and eosin $\times 55$.

infiltrating as the others. In the lesions of grade 3 and 4 malignancy the picture corresponded to the alveolar pattern described in the literature (Fig. 5). Here papillary formations were for the most part absent and only poor glandular formation was apparent. Mitotic figures were numerous and frequently atypical forms were seen. Giant tumor cells perivascular growth, the occurrence of zones of necrosis and the plugging of lymphatic spaces (2 cases) and blood vessels (1 case) bespoke marked degrees of malignancy (Fig. 6). In 8 of the cases the entire growth appeared to be localized within the confines of the stretched-out tubal peritoneum whereas

in the remainder there was evidence of extension with frequent involvement of what the surgeon described as surface adhesions.

In common with other investigators we found an almost 100 per cent incidence of subacute or chronic inflammatory changes in the so-called normal portions of tubes that were the seat of carcinoma. However we were unable as a result of our studies to decide whether the carcinoma developed secondarily or whether the inflammatory process represented a reaction to the necrosis resulting from the breakdown of malignant tissue. The former possibility has been proposed and it is supported by (1) the occurrence of carcinoma in the ampullary portion of the tube which is the seat of election for the development of tubal inflammation and (2) the finding of hydrosalpinx, pyosalpinx, and hematosalpinx in the contralateral tube as noted in 9 of our cases.

The concomitant occurrence of tubal tuberculosis and tubal carcinoma has been emphasized in the literature (8, 10) and an etiologic relation has been postulated. However it is well known that tuberculous salpingitis is frequently productive of marked epithelial hyperplasia often with the formation of papillary and alveolar configurations. The appearance may suggest carcinoma and indeed in 2 of our earlier cases the condition had been so labeled. These 2 cases were eliminated from our series because although the archi-

Fig. 7. Tubal tuberculosis illustrating the concomitant epithelial hyperplasia. Such sometimes misguides the pathologist to making the additional diagnosis of carcinoma. Hematoxylin and eosin $\times 8$.

ture when seen under low power magnification suggested a malignant process associated with tuberculosis examination under high magnification failed to reveal cellular atypia mitotic figures lymphatic invasion and the other criteria of malignancy which were so prominent in other cases (Fig 7) In 1 of our cases tuberculous salpingitis involved the contralateral fallopian tube

None of the tumors seemed to arise in connection with tubal endometriosis. Tubal adenomyoma was demonstrated in 1 of our specimens but at some distance from the carcinoma Work and Broders (5 31) have shown that tubal adenomyomas involve principally the uterine or isthmic portions of the tube and that the lesions are nearly always bilateral The location and distribution of these lesions are accordingly unlike that of primary carcinoma of the tube No etiologic relation between tubal polyps and tubal carcinoma was evident from the examination of our material

End results of treatment Two of 16 patients are living 10 and 14 years after operation In both of these cases the lesions were small and there was no extension beyond the presence of an ovarian nodule in 1 case in which the ovary was attached to the fimbriated end of the tube Nine of the patients are known to be dead The average postoperative survival in this group was 18 months with extremes of 4 months and 5 years All grades of malignancy were represented in this group with the duration of survival being generally longer when the grade of the tumor was low rather than high Postoperative roentgen therapy appeared to delay the fatal outcome in 1 of these 9 patients. Four of the patients have been operated on too recently to permit conclusions as to prognosis but the presence in 2 of peritoneal implants does not suggest a happy prospect The 16th patient has not been heard from It is accordingly apparent in our series that primary tubal carcinoma carries a gloomy outlook from the standpoint of successful treatment. A high grade of malignancy the presence of peritoneal metastasis and the finding of malignant invasion of lymphatic spaces and of blood vessels appeared to be unfavorable features.

SUMMARY AND CONCLUSIONS

Primary carcinoma of the fallopian tube is a rare condition which accounts in our experience for only 1 out of every 625 carcinomas of the female genital tract. For the most part it is a disease of the menopause and has not been reported among individuals in their prepuberal years Symptoms are insidious in their onset with vaginal discharge pelvic pain and abdominal tumor representing cardinal symptoms which however rarely lead the physician to a correct preoperative diagnosis. The evolution of the disease is more rapid than is indicated by its symptomatology and the majority of patients so afflicted demonstrate lesions of doubtful resectability at the time of surgical exploration The appearance of the lesion on gross inspection is sometimes deceiving since it may mimic closely familiar tubal conditions of an inflammatory nature Because of this every distended fallopian tube should be opened before it is removed from the operating room Treatment of these carcinomas whenever found regardless of any apparent state of encapsulation should consist of total abdominal hysterectomy with bilateral salpingo-oophorectomy in addition to removal of any discernibly involved regional lymphatic nodes and peritoneal implants. Postoperatively roentgen therapy should be administered In spite of these measures the number of 5 year cures is disappointingly small Pathologists who are unfamiliar with the condition will often have difficulty establishing the primary nature of the lesion and should remember that the fallopian tubes are frequently involved in metastasis from ovarian and uterine sources. Actual involvement of the tubal mucosa strict confinement to the fallopian tube a marked disproportion between the size of the tubal and extratubal lesions as well as a working knowledge of the histologic pictures of primary uterine tubal and ovarian carcinomas will be helpful in deciding the primary source in doubtful cases The epithelial hyperplasia associated with tuberculous salpingitis should be kept in mind and the diagnosis of tubal tuberculosis and carcinoma should not be made except when malignant neoplasia is manifestly indicated

SPONTANEOUS RUPTURE OF THE SPLEEN

J B LITTLEFIELD Sr MD F.A.C.S Lieutenant Colonel MC A.U.S., Tucson, Arizona

SPONTANEOUS rupture of the spleen a serious condition which demands careful clinical evaluation and prompt surgical intervention is relatively uncommon and therefore may be difficult to diagnose. In the hope of stimulating interest in this subject 3 cases are presented to demonstrate this difficulty in diagnosis. Two of the cases are from personal experience and the third is reported from a clinical summary received from another hospital.

CASE 1: An enlisted man, 19 years old, was admitted to the hospital on August 17, 1943. He had served in the Army 4 months. His home was in Philadelphia, Pennsylvania. He complained of vague basal headaches, abdominal pains, and a cold. The headaches, which started soon after he was inducted into the Army, would last from 1 to 12 hours and would then disappear. He had rarely ever had a headache before induction. During these attacks his stomach was upset and he could not tolerate food. In addition he complained of shortness of breath. There was nothing significant in his past history. He was slender, 6 feet tall, and weighed 130 pounds. He had mild acne, his nose, nasopharynx, and tonsils showed a mildly acute infection. His chest and cardiovascular system were normal, the blood pressure being 110/64. The only positive findings were a generalized lymphadenopathy and an enlarged spleen. No abdominal tenderness was noted. Infectious mononucleosis was suspected and ruled out. The Wassermann test for syphilis was negative. The initial impression, as noted by the ward surgeon, was that the man was suffering from psychoneurosis and acute nasopharyngitis.

From August 17 until August 23, 1943, he ran a low grade temperature and developed a frank follicular tonsillitis. A course of sulfadiazine treatment, consisting of a total of 3 grams, was given during this period. The lymphadenopathy and enlarged spleen did not change perceptibly.

At approximately 11:30 o'clock on the morning of August 23, while returning from the latrine in the ward, he felt a sudden, severe pain in the upper left abdominal quadrant, became very weak, and barely managed to get on his bed, when he collapsed. He was seen immediately by the ward surgeon, who found him pale, cold, and clammy; his pulse was slow but weak. The blood pressure was 70 systolic and 40 diastolic. Tenderness was noted in the left lumbar region and over the spleen. His condition was that of typical hemorrhage and shock.

The intravenous administration of blood plasma was started immediately and the foot of the bed was elevated. He was seen by the chief of the medical service in consultation, and we both felt that he was suffering from an intra-abdominal hemorrhage most likely coming from the spleen. Five hundred cubic centimeters of citrated blood was given him. During the following 2 or 3 hours his blood pressure rose to 100/80, and the signs and symptoms of acute shock subsided.

In the interim definite generalized tenderness developed over the abdomen, and we had the definite impression of shifting dullness in the abdomen on postural changes. The

total red blood cells and hemoglobin decreased and the white cell count increased. At first there was a polynuclearleukocytosis on differential count, but later we observed a definite reversal of the leucocyte lymphocyte ratio (Table I).

At 8:30 p.m. we decided to operate, but the patient refused. Operation was therefore delayed until we could reach his father and mother in Philadelphia and obtain their consent to operate.

Pentothal sodium was given the patient while he was in bed, and this was supplemented in the operating room by ether administered by the closed method.

Operation was started at 1:03 a.m. and ended at 1:44 a.m. August 24, 1943. An incision approximately 7 inches long was made over the middle of the upper left rectus muscle, extending from the costochondral angle to the level of the umbilicus. The abdomen was opened and a large quantity of dark blood was encountered. The spleen was found lying laterally against the abdominal wall. A large rent on its curved surface extended from the upper to the lower pole. It was delivered out of the abdomen and digital control was used on the pedicle until a series of clamps were applied. The pedicle was then divided and the spleen was removed. A mass ligature was placed around the pedicle, and each vessel was ligated separately distal to it. The raw surface was peritonized. Several double handfuls of clots were removed from the left trough in the region of the left kidney. The abdomen was then closed without drainage. During the operation 500 cubic centimeters of citrated blood was given. He returned to his bed in excellent condition.

Following is the pathological report (Figs. 1 and 2). The specimen consists of a spleen immersed in normal saline measuring 16 by 12 by 7 centimeters. On the diaphragmatic surface is a huge, gaping capsular rupture running the entire length of the spleen and measuring 8 centimeters across. This rent is covered by large shaggy clots. Cut section shows indistinct markings. It is impossible to identify the follicles. The pulp is bright, pinkish red. The capsule is thin, the consistency very soft.

Microscopic examination revealed the following. The follicles are enlarged and not sharply demarcated. The pulp is cellular with increase in the monocytic elements. The sinusoids are collapsed and contain little blood. The capsule is thin. A laminated thrombosis covers the torn splenic surface.

Diagnosis: ruptured acutely hyperplastic spleen.

The postoperative course was very stormy and hectic. On the day following operation he was given a third transfusion of 500 cubic centimeters of citrated blood. From this time his red cells and hemoglobin stayed normal or above. Two days following surgery his temperature arose to 107 degrees F. but was easily controlled by covering him with a wet sheet and allowing an electric fan to blow on him. X-ray pictures at this time showed evidence of pneumonia in the left base. Treatment with sulfadiazine, 1 gram every 4 hours, was instituted. His temperature became normal 5 days after the operation. The sulfadiazine was discontinued the next day. On the following day a typical sulfadiazine rash appeared which desquamated as time went on.

On September 4, 1943, the wound separated down to the deep fascia. A course of treatment consisting of vitamins B and C followed.

Fig. Diaphragmatic surface of spleen.

Throughout September 1941 there were episodes of low grade fever, anorexia, etc. Repeated examinations for undulant fever, malaria and the typhoid group were all negative.

During October he began eating better, gained eight and strength. He was transferred to the convalescent barracks. He began to complain of his earlier headaches and vague abdominal pains.

Finally, on December 9, 1941, he was given a certificate of disability discharge because of psychoneurosis, severe.

CASE 2. On November 5, 1941 an officer aged 24 years, entered the hospital, complaining of soreness in his upper left abdomen and weakness. Ten days before entering the hospital, after doing "tumbling act" in the gymnasium with other officers, he noticed severe pain in the upper left quadrant of the abdomen, which was followed by diarrhea. The soreness persisted but he was constipated for 4 days. Diarrhea occurred again followed by 3 days of constipation. The pain "feels like steady cramp," he said. By this time our staff had become "ruptured spleen" conscious. When the attending surgeon secured this history and found an enlarged tender spleen, he immediately admitted him to the hospital. On admission his blood count was 5,000,000 red blood cells, 4,200 white blood cells, polymorphonuclears 8 per cent, and lymphocytes 9 per cent. A transfusion of 500 cubic centimeters of citrated blood was given.

He was observed carefully during the next 36 hours. On this time in spite of the transfusion, his red blood cell count gradually fell. It was felt that the man was having slow intra abdominal hemorrhage probably splenic in origin. The chief of the medical service and I were very much interested in the reversal of the leucocyte lymphocyte ratio at this time (Table II).

After due consideration, operation was decided on, and was performed at 3:30 p.m. on November 20, 1941. Incision was made in the left paramedian line extending from the costophrenic angle to the level of the umbilicus, thus opening the abdomen. There was slight evidence of hemorrhage present. A self retaining retractor was placed in the wound. The anterior surface of the liver and gall bladder appeared normal. The abdominal contents were then gently pushed downward and to the right, exposing a very large spleen surrounded by free blood and blood clots. The dome of the spleen was found adherent to the diaphragm. These adhesions were broken down by blunt finger dissection. They were caused by an organized clot between the spleen and diaphragm. There was small rent on the dome of the spleen, which was bleeding. After delivery of the spleen from the wound, blood was seen coming from the splenic vein in the hilus. Three clamps were applied to the pedicle and it was cut between the distal and proximal ligatures were placed on each end and the raw surface was pentonized. All blood clots were removed from the splenic fossa. The liver and sur-

TABLE I.—LEUCOCYTE LYMPHOCYTE REVERSAL IN CASE I

Fig. 3. Hilus of spleen.

rounding viscera were carefully examined for bleeding points, but none was found. The abdomen was closed and the patient was sent back to bed in excellent condition. Five hundred cubic centimeters of citrated blood was given during the operation.

Pathological report. The specimen consisted of a spleen immersed in formalin measuring 18 by 11 by 8 centimeters. On the diaphragmatic surface near the upper pole a 30 by 8 millimeter firmly adherent dark red clot was seen which extended into the splenic substance for a distance of 4 millimeters as a sharply defined red area. On the anterior margin nearer the lower pole two adjacent nodular 15 by 3 millimeter subcapsular hemorrhages bulge slightly above the general level. On section they are sharply defined and dark bluish red. The splenic markings on cut section are indistinct and deep red.

Microscopic examination revealed the following: Two large subcapsular hemorrhages were present. At another site the capsule was ruptured with a fragment lifted away over the blood clot with bands of fibrin. The follicles were indistinct. Both follicles and pulp were cellular. No abnormal cells were found. The sinusoids were congested with blood.

Diagnosis ruptured hyperplastic spleen with hemorrhage.

We are not as sure about the pathological condition here as we were in the first case. There were both new blood and an organized clot about the spleen. The spleen was adherent to the diaphragm by an organized clot. The small tear seen in the capsule at operation and the bleeding from the splenic vein could have been more recent and due to handling. In view of the fact that no other hemorrhage was found and the patient's bleeding stopped following removal of the spleen we are at a loss for any other explanation.

There is also a vague history of trauma here whereas the other case was spontaneous on a basis of sepsis (6).

The postoperative course was stormy but not as bad as was the previous case. Wangersteen suction was used for 4 days.

On the tenth postoperative day a friction rub developed at the base of the left lung. This was followed by pleural effusion. Aspiration had to be done approximately 35 days postoperatively. Following this the lungs cleared rather rapidly (Figs. 3 and 4). He was granted a sick leave of 30 days, 3 months following the splenectomy. On his return his chest was negative and his blood picture was normal. He returned to full duty.

In the report of the Ninth Service Command for the week ending November 20, 1943 a case of spontaneous rupture of the spleen was recorded. We requested information from the hospital in which it occurred and received a complete case report. The following is a brief résumé of the case.

TABLE II.—LEUCOCYTE LYMPHOCYTE REVERSAL IN CASE 2

Date	Time	Rbc	Wbc	Hb-gm	Poly %	Lymphs %
2-44	Out patient	4,350,000	6,000	3	60	
3-44	Admitted to hospital	3,000,000	4,200		3	9
3-44	Given 500 cc citrated blood					
26-44	9 am	3,850,000	1,000		75	24
26-44	3 pm	3,700,000	10,000		75

28-44		4,800,000	6,000		65	12

Fig. 3. Roentgenogram showing pleural effusion in left base.

CASE 3. An officer aged years, was admitted to the hospital November 4, 1943, 1:00 p.m. He gave history of feeling below par for 3 weeks. The only specific complaint was that of malaise and constipation. He had noticed transient abdominal pain on November 3, 1943, but continued to work. At 7:00 p.m. on November 4, 1943, two hours before admission to the hospital, he vomited several times, and had severe abdominal cramps.

On physical examination he was pale, his breathing was rapid, pulse 84, and his blood pressure was systolic 90, diastolic 49. His heart tones were poor. He showed moderate abdominal distention, peristalsis could be heard, but no masses were palpable. There are no areas of localized tenderness.

X-ray picture of the chest as reported. His urine was normal and his blood count was: red blood cells, 3,650,000; white blood cells, 4,400; polymorphonuclears 84 per cent, and lymphocytes 6 per cent. He continued to grow weaker. At 10:00 p.m. on November 5, 1943, he was operated under spinal anesthesia. A very large, soft, friable spleen, 13 cm. in length, was removed. Two thousand cubic centimeters of blood and lots of clots were removed. During the operation and immediately following it, he received 1,000 cubic centimeters of plasma and 1,000 cubic centimeters of citrated blood. At end of operation his blood pressure was 100/50 and his pulse rate was 120.

The pathological report follows. Specimen consists of spleen which has been sectioned and partly crushed by being forced into a small bottle so that the external shape cannot be made out. The splenic tissue together weighs 470 grams. In some places the capsule is elevated by small blood clots. The splenic tissue is poorly fixed except just beneath the capsule where small malpighian bodies can be made out. They are widely separated. The splenic pulp in the center of the organ is extremely soft, at least partly due to autolysis. Microscopic examination reveals marked diffuse cellular overgrowth of the pulp which widely separates the malpighian bodies and apparently infiltrates them at their periphery in most instances. Throughout the pulp there are seen numerous channels which are lined by endothelium. There is no evidence of increased connective tissue. In the pulp there are seen few plasma cells and rarely other mature leucocytes. The predominating cell is a fairly large mononuclear cell with deeply stain-

Fig. 4. Increased thickness in left diaphragmatic area after removal and absorption of pleural effusion.

ing nucleus and in most instances a relatively small amount of cytoplasm. Some of these cells have larger amounts of cytoplasm and distinct cell outlines. There are frequent mitotic figures and many of the immature cells show fairly prominent nucleoli. Reticulum stains of the spleen show slight variation in the amount of reticulum in different portions of the spleen, however there is no great increase and it is questionable whether there is any increase in reticulum. A relatively small number of the cells are surrounded by reticulum.

Interpretation: reticulum cell sarcoma of spleen.

By November 7, 1943, he had developed pneumonia in the left base and was placed in an oxygen tent. He was given sulfadiazine and other supportive treatment. Twelve days after operation after a severe coughing spell, the wound separated. This was closed under pentothal anesthesia. He never walked and died in spite of all supportive measures.

At autopsy the following findings are recorded: (1) pneumonia, lobes: lower lobe left, upper and lower lobes right; (2) pleurisy acute serofibrinous thickening, left severe secondary to lobar pneumonia, (3) embolism, or organized thrombus, right pulmonary artery severe probably secondary to lobar pneumonia (4) surgical absence of spleen.

SUMMARY AND CONCLUSIONS

1. Spontaneous ruptures (4) occur in the soft overdistended spleen of acute fevers, like malaria typhoid, typhus, acute septic splenitis and infectious mononucleosis. A rupture is said to be spontaneous (2) when it happens without apparent trauma or after the insignificant trauma of muscular exertion.

2. The 2 original cases of this report showed a reversal in the leucocyte-lymphocyte ratio before surgery which corrected itself soon after surgery.

(Tables I and II) In the last edition of *Physiological Bases of Medical Practice* by Best and Taylor the statement is made "The spleen serves three well recognized purposes namely (1) the final destruction of blood cells (2) the storage of blood and (3) the manufacture of lymphocytes in the lymphoid tissue composing the malpighian corpuscles. Immediately after operation there is usually a leucocytosis reaching as high as 30,000. At first the polymorphonuclears predominate but as the total count approaches normal there is usually a reversal and the lymphocytes predominate. Klemperer and Hirschfeld suggested that this action might be accounted for by removal of an organ where pressure, possibly hormonal, exercised a depressant action on the bone marrow. Bertell, Falta and Sweeger point out that the changes in the peripheral blood may also be brought about by the injection of substances which increase the tone of the autonomic or of the sympathetic nerves. Careful review of available literature did not reveal an instance of this reversal being recorded in a case of a bleeding ruptured spleen before its removal. In both of our cases repeated blood counts were made and the hemorrhage was sufficiently slow to permit this change before surgery.

3 Each of the 3 cases mentioned developed pleural and pulmonary complications. It started as pleurisy in the left base. In the second case pleurisy with effusion predominated. Since the

curved side of the spleen is against the diaphragm on the left side the irritation from the hemorrhage and from the trauma of the surgery causes a splinting of the diaphragm which invites stasis and localized atelectasis in the base of the left lung thus bringing about pneumonitis and pleurisy (Figs. 3 and 4).

4. Two of the patients had wound separation. In both of these the chest complications came on early with coughing. In the second case the chest complications manifested themselves after the wound had healed and the coughing did not disrupt the incision.

5 Embolism is a very common complication. It was probably the immediate cause of death in the third case report.

The splenic veins frequently become thrombosed. Since the splenic and the superior mesenteric veins unite to form the portal vein embolism may give rise to septic pyelophlebitis of the liver (5).

ACCIDENTAL TRANSPLANTATION OF CANCER IN THE OPERATING ROOM

With a Case Report

W W BRANDES M D W C WHITE, M D F.A.C.S and J B SUTTON M D
New York New York

THE literature contains many references to local recurrence about the operative site, of cancer of the breast and of other organs. Ryall (3) nearly 40 years ago pointed out that recurrence was frequently due to contamination of the instruments used in operation with the cells from the tumor being removed. He cited a series of cases in which cancer of the breast, tongue, lip, larynx, rectum and colon were reimplanted at the operative sites through cancer infection of the wounds by contaminated knives and needles. He mentioned the post-operative occurrence of a distant nodule in the axillary fold following a radical mastectomy when a stab wound for drainage of the operative site was made with the knife which had been used in the mastectomy and concluded that it was therefore of the utmost importance to guard against the danger of implanting these cells into any fresh wound. In 1908 (4) he recommended a complete change of gloves, drapes, and instruments, and reparation of the operative site after biopsy of a malignant tumor has been completed and the exploratory incision closed. This recommendation has been made repeatedly since then, having been especially emphasized by Ewing in 1933 and by Saphir in 1936.

Saphir presented objective evidence of the presence of viable tumor cells on knives used for biopsies; he made smears directly from knife blades and from saline in which such blades had been rinsed. He found large numbers of tumor cells on blades used to incise tumor masses, and on those used to remove the tumors for biopsy prior to radical mastectomy. He demonstrated the viability of the cells by means of supravital staining according to the method described by Hickling. Thus, the presence on instruments of tumor cells, viable and capable of transmitting the cancer infection to other parts of the operative wound, which for many years had been assumed, was clearly demonstrated.

From the Departments of Pathology and Surgery, The Roosevelt Hospital, New York.

Tumor growth is occasionally seen at the site of paracentesis or thoracentesis wounds in carcinoma of the peritoneum or pleura. We have seen this in 2 instances in the past 2 years.

The operators' gloves must obviously be another convenient means of transfer of tumor cells, and we wish to report here a case in which it seems evident that contamination of the gloves was responsible for transplantation of a highly malignant carcinoma of the breast from the mastectomy site to a skin donor area on the left thigh. We have seen no previous report of transfer to so distant a site.

CASE REPORT

Mrs. M W, 47 year old office receptionist, entered The Roosevelt Hospital on May 9, 1944, as patient of Dr. W C. White. Ten months previously she had noticed a small lump in her right breast, which had grown slowly. More recently her doctor had discovered axillary nodes.

Physical examination revealed a 5 centimeter nontender lump in the right breast, situated 1 1/2 clock, about 4 centimeters from the nipple. Its mobility was slightly limited, but it was not actually fixed to the impression of being attached to the underlying fatty tissue but not to the fascia. There was faint trace of dimpling of the skin over the tumor on movement. Three hard, nontender, freely movable lymph nodes could be felt in the right axilla, and smaller firm nodes were found in the left axilla and the right supraclavicular region.

On the second hospital day radical mastectomy was performed, with immediate skin grafting.

A radial incision was made over the tumor, high to gather the generous amount of surrounding fatty tissue as excised with the high frequency needle. The tumor itself was not incised. Frozen section revealed carcinoma. The biopsy wound was closed with silk and the patient was redraped, the operative area having been painted again with mercuric iodine. The operator, his assistants and the instrument nurses changed their gloves and gowns, and another set of instruments was substituted for those used in excising the tumor. A circular incision was then made about the tumor with the radius of about 1/2 inches, in order to avoid nicking or approaching the tumor site. The wound was extended obliquely downward toward the abdomen, after which the nipple skin, breast tissue, thoracic portion of the pectoralis major and the pectoralis minor and the axillary contents from the apex of the axilla, downward and out and out, were removed. The wound edges were sutured to the chest wall, leaving a large area, irregular in outline and measuring roughly 7 by 10 centimeters. A Padgett skin

graft .008 inch in thickness, was then removed with a dermatome from a previously prepared donor site on the left thigh, and the graft was sutured to the wound edges with interrupted silk, punctured in many places, and dressed with a cellulose sponge for pressure. The donor area was dressed in a similar manner.

After the mastectomy and before the skin grafting was done, the operating and assistant gloves were washed in distilled water, but were not changed.

Pathological examination of the tissue showed a tumor mass measuring 3 by 3.5 centimeters, irregular in outline, unencapsulated, and extending into the surrounding fatty

tissue. Diagnosis was scirrhous carcinoma of the breast, grade III, with metastatic involvement of axillary lymph nodes (Fig. 1). Neither the tumor mass nor the involved nodes had been directly incised by the operator.

During a rather slow postoperative recovery, additional nodes were removed from the posterior triangle of the neck on the right side, and on examination these also revealed metastatic carcinoma. Epithelialization of the donor site on the thigh was slow, and the patient's general condition did not warrant discharge from the hospital until the 8th postoperative week. X-ray examination of the chest made just before discharge was negative.

One month later the patient was readmitted in stat of cachexia. X-ray studies at this time showed widespread metastatic involvement of lungs and bones, and there were local skin recurrences at the mastectomy site. Her course was rapidly downhill, and she died on the 32nd hospital day.

At autopsy the patient was pale, cachectic, weighing about 80 pounds. Multiple skin recurrences were noted along the mastectomy scar at the lines of incision and at the sites of suture wounds. Multiple metastases were seen throughout the chest cavity, particularly on the right, the right pleura, lung, pericardium and mediastinal nodes were involved, and there was a nodule on the wall of the right auricle.

The skin donor site on the left anterior thigh was studded with firm, discrete irregular nodules, the largest being about 0.5 centimeter in diameter (Fig. 2). Microscopic examination of these nodules revealed carcinoma similar to that seen in the primary breast tumor (Fig. 3).

The possibility of metastatic transfer by way of the blood or lymph stream from the breast to the skin of the thigh is too remote to be considered, and since no instruments were used both at the breast site and at the donor area, the gloves of the operator and his assistants must obviously have been the means of transfer of tumor cells. We have previously pointed out that the gloves were washed in the basins of distilled water provided in the operating room for that purpose after the mastectomy and before the removal of the dermato-tome graft from the thigh. Merely washing the gloves in this manner is obviously an insufficient precaution; the tumor cells may not be completely removed from the gloves, and in any event the washing fluid is contaminated with them. The gloves, still wet with this fluid, must thus be assumed to be contaminated.

We have centrifuged the contents of such basins, the fluid having a volume of $2\frac{1}{2}$ to 3 liters, and have found well preserved tumor cells in the sediment. It is not necessary that the tumor be handled deliberately. In 1 instance easily identifiable tumor cells were demonstrated in the fluid after a radical dissection of the right inguinal region for removal of tumor-bearing inguinal nodes (Fig. 3); the primary tumor a poorly differentiated squamous cell carcinoma had previously been removed from the dorsum of the foot between the toes. Since the nodes were not incised the contamination must have resulted from the opening of involved lymph channels, which obviously cannot be avoided. The accidental transfer of malignant tumor cells from an operative site to a distant part of the body can be avoided by changing gloves and avoiding the use of contaminated washing fluid after the tumor-bearing area has been handled.

Cells have also been found in a number of cases in the fluid used during operation for carcinoma

of the breast (Figs. 4 and 5). In cases in which the tumor has been handled directly and incised, the cells are more abundant as is to be expected. When distilled water was used it was necessary to centrifuge the fluid and make the smears rather soon after the washing in order to obtain well preserved cells. Cells left in distilled water for more than about 30 minutes before the fluid is centrifuged often become swollen and even disintegrated; such cells are probably nonviable. Even with distilled water, however, it should be possible to transfer viable cells when repeated washing of gloves is done at short intervals, when more than one operator uses the same basin, or when gloves are changed and the fluid used to wash the original gloves is again used to remove powder from the new pair before returning to the operation. When normal saline is used cells apparently remain viable for longer periods.

We have had no difficulty in verifying and repeating the work of Saphir. Tumor cells were demonstrated not only on the blades of knives used in resection or biopsy of malignant neoplasms, but on clamps and tenacula used to grasp breast tumors or to catch bleeding vessels adjacent to them.

SUMMARY

A case is reported in which, several months after a radical mastectomy for a highly malignant scirrhous carcinoma of the breast, cancer nodules were found in the skin of the donor site on the opposite thigh. The usual precautions had been taken after biopsy of the tumor and before the mastectomy, viz., changing of operators and nurses' gloves, and redraping and reoperation of the patient. However after the mastectomy when a defect in the skin over the operative site was to be covered a skin graft was taken from the left anterior thigh without first changing the contaminated gloves used at operation. Washing the gloves in sterile distilled water was apparently insufficient and tumor cells were transferred from the operative site to the raw donor area, where they survived and gave rise to tumor nodules.

Previous work in which tumor cells have been demonstrated on knives used for biopsies is reviewed and it is also shown that the fluid customarily used in the operating room to wash the gloves of the operators is another potential source of contamination of distant parts with malignant tissue.

INTERCORPORAL BONE GRAFT IN SPINAL FUSION AFTER DISC REMOVAL

IRWIN A. JASLOW M D Sayre, Pennsylvania

FUSION of the adjacent vertebrae following the removal of degenerated discs is gradually being accepted as the proper procedure. In clinics where simple removal of the disc without fusion is performed the results are poorer than in those where the combined procedures are done. Due to this fact many more fusions are now being performed. Frequently patients who did not have fusions initially have returned for secondary fusions because of persistent low back pain long after the sciatic radiation had been relieved by removal of the degenerated and protruded disc. Other undesirable sequelae following disc removal without fusion have been illustrated in a recent paper by Graf and Hamby.

On both a theoretical and practical basis, fusion is indicated. Theoretically fusion should be performed because the low back pain which antedates the onset of radiating pain to the buttock or leg by months or years in the majority of cases indicates an instability in the lower spine. In addition, there are multiple anomalous developments of facets of the fifth lumbar vertebra and to a lesser degree the fourth. Their asymmetry and the fact that they are the last and most vulnerable movable segments attached to the pelvis indicate the desirability of fusion. These are the factors which seem to cause the high incidence of degeneration of intervertebral discs at these levels, eventually resulting in protrusion and pressure on nerve roots. We can recall many patients who were completely relieved of their symptoms by simple fusion done after a diagnosis of unstable fifth lumbar vertebra was made, with or without sciatic scoliosis. The latter we now know as a protective list. A review of the histories and physical findings in many of these patients reveals data identical with that of patients whom we now know to have sciatica from disc pressure. It can be assumed, since they were completely and permanently relieved without removal of the disc, that they could have had incompletely protruded discs or discs which caused nerve root pressure only in certain positions. At operation or in bed following the

fusion such discs probably returned to their normal positions and after fusion took place between the vertebral laminae were incarcerated in the disc space. Without intervertebral motion they could not protrude again.

It has been stated in some quarters that a fusion operation in itself is unnecessary, since thorough curettage of the disc space will allow the vertebral bodies to fuse. The proof for such a statement is lacking and vertebral fusion has been rarely demonstrated except in a few cases complicated by infection. The removal of the intervertebral disc and cartilage leaves a space between the vertebral bodies, the ideal situation for nonunion. The writer has had the opportunity to see several patients who came to fusion after discs had been removed elsewhere. In all of these cases motion between the adjacent vertebrae was readily demonstrated by pressure on the spinous processes at the time of operation.

This paper is a description of an adjunct to spinal fusion after disc removal.¹ A peg of bone is driven in between the vertebral bodies into the space from which the degenerated disc and cartilage plates have been removed. It is felt that this peg serves several useful functions: (1) It maintains the height of the disc space so that there will be no pinching of the nerve roots in the intervertebral foramina. Indeed in several cases in which the preoperative films revealed narrow disc spaces the postoperative films taken 6 weeks later revealed definite widening of the involved spaces. (2) The space left by removal of disc and cartilage is partially taken up by the peg so that there is no distraction and the space that would ordinarily be filled with blood clot and eventually fibrous tissue is partially taken up by an osteogenic bone graft. These factors tend to promote bony union between vertebral bodies. (3) The placing of the peg into the intervertebral space under forced flexion provides increased stability which allows earlier mobilization of the patient without fear of pseudarthrosis.

Operative procedure (Fig 1) With the patient lying prone and the lumbar spine flexed acutely

The idea for the use of the bone peg was the result of discussion with D. Henry Briggs of East Orange, New Jersey. It was under his supervision that the first bone peg was inserted in 1945, at the New Jersey Orthopaedic Hospital.

From the Section on Orthopedic and Traumatic Surgery, Guthrie Clinic and Robert Packer Hospital, Sayre, Pennsylvania.

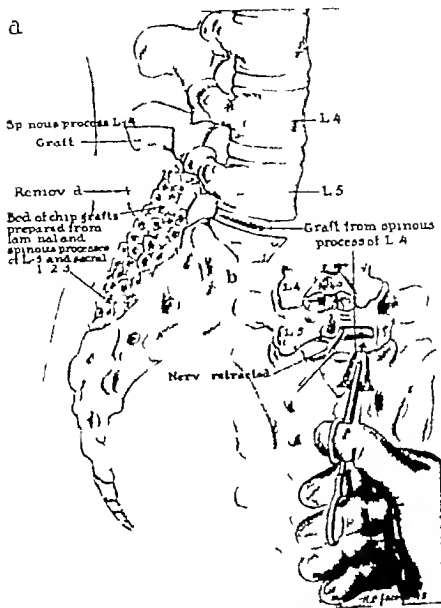

Fig. 1. a, The position of the posterior bone graft is shown. b, The manner in which the graft is inserted is demonstrated, diagrammatically (The nerve root is not retracted quite so vigorously in operation).

the lumbosacral spine is exposed subperiosteally through a midline incision from the third or fourth lumbar level to the level of the spinous process of the third sacral segment and laterally to the facets. A self retaining retractor is placed. For the exposure of the fifth lumbar disc the spinous processes of the fifth lumbar and the upper sacrum are removed flush with the lamina with an osteotome or heavy rongeur forceps. Ligamentum flavum and enough bone to permit the passage of a finger tip are removed from the

affected side of the interlaminar space to reveal the bulging or herniated disc pressing on the first sacral nerve root. If the disc appears normal and no nerve pressure is demonstrated the fourth lumbar disc is explored in similar fashion and the spinous process of the fourth lumbar vertebra removed. When the disc causing nerve root pressure is found, it is removed with a pituitary rongeur either through the hole in the annulus fibrosus through which it ruptured in the case of the herniated disc or through a hole cut in the

Fig. 2. The bone graft in position in the fifth lumbar disc space, 6 weeks postoperatively

annulus fibrosus in the cases of the bulging and hidden discs. The disc space is then thoroughly curetted to remove the remaining disc material and cartilage plates of the vertebral bodies. Care is taken to stay within the intervertebral space.

A rectangular peg is fashioned from the spinous process of the vertebra above. This is usually about 2 centimeters long and slightly higher than the estimated disc space. By levering on the adjacent lamina the former disc space is widened enough to allow this peg to be inserted into place. It is then rotated 90 degrees by means of a small curet so that the long axis is broadside to the hole in the annulus fibrosus through which it was placed. This diminishes the possibility of its being pushed back into the spinal canal. In the more recent cases, up to four pegs have been placed in the same disc space. The exposed nerve root which was retracted medially is allowed to return to its normal position and is covered with a piece of subcutaneous fat. Muscle or a thrombin coated absorbable starch sponge is used in troublesome hemorrhage.

A modified Hibbs or chip fusion is now performed. The facets are thoroughly curetted free

Fig. 3. The bone graft in position in the third lumbar disc space, 3 weeks postoperatively. The posterior fusion mass between the third and fourth lumbar vertebrae is well demonstrated. (In this case pantopaque myelography was performed because of bizarre neurological findings indicating that the lesion was not at the fifth or fourth lumbar disc. About two-thirds of the pantopaque was removed.)

of cartilage and bone chips are turned into the apophyseal joints. The laminae of the most superior vertebra to be fused are turned up cephalad in the form of a buttress. More bone chips are cut from the laminae of the caudal vertebrae with a gouge until no cortical bone is visible on the upper sacral and lumbar laminae to be fused. To these chips are added others cut from the previously removed spinous processes.

After wound closure the patient is placed in a firm bed without other support. He is allowed up in 3 to 6 weeks, usually with a light brace or canvas support. In recent months 2 patients have left the hospital without brace support, because they were unwilling to wear one. They have suffered no ill effects and follow up roentgenograms demonstrate satisfactory progression toward fusion.

Since the procedure described has been in use for only 2 years, no attempt is made to evaluate

THE INITIAL SURGICAL TREATMENT OF PENETRATING WOUNDS OF THE RECTUM

HAROLD LAUFMAN M.D. I.A.C.S. Major M.C., U.S. Chicago, Illinois

THIS communication is based upon a series of 35 consecutive cases of penetrating wounds of the extraperitoneal portion of the rectum operated on at an Evacuation Hospital during the Italian campaign. Its purpose is to emphasize certain phases of the diagnosis, anatomy and surgical treatment of these wounds and to pose some questions relative to factors governing their management.

Missiles entering the body anywhere between the levels of the lower thigh and the costal margin have been known to penetrate the rectum. This is especially true of wounds of the dorsal surface of the body. Wounds of the buttocks, hip area, sacral area and posterior thighs are extremely common in warfare because of the prone position a soldier usually assumes while under fire. While wounds of these regions are most likely to involve the rectum, the incidence of rectal penetrations fortunately is relatively very low. In our experience, only 6 per cent of buttock wounds penetrated the rectum. Because of its protected anatomical location the rectum will usually escape injury unless the missile has crossed or has lodged near the midline.

The patient with a penetration of the extraperitoneal portion of the rectum may present no symptoms referable to this organ at the time of initial examination. Consequently, unless a thorough appraisal of the case is made prior to surgery the lesion may be overlooked. It is important to study the pathway of the missile by inquiring into the position of the patient at the time of injury and by careful examination. It hardly seems necessary to emphasize the warning that in studying roentgenograms one must make sure of right and left sides. Yet it is easy to assume that a foreign body lies on the same side as the wound of entrance, unless this point is checked. When roentgenological evidence indicates that a pelvic foreign body has traversed the midline, suspicion should be directed immediately toward the possibility of rectal injury. When no foreign body is demonstrable in the films, re-examination of the patient is imperative to ascertain the location of the wounds of entrance and exit, and to reconstruct the possible course of the missile. In one of our patients a shell fragment

had entered the body above the left iliac crest, perforated the rectum and emerged on the lateral aspect of the lower third of the right thigh. From the appearance of the wounds they seemed to be two completely unrelated penetrating wounds.

What often appears to be an innocuous wound of the buttock or thigh not infrequently is found to penetrate the rectum. The same warning has been made repeatedly in regard to wounds which penetrate the abdominal cavity via the buttocks and has resulted in routine abdominal examinations of patients with buttock wounds. However, in the event that the abdominal cavity does not appear to be penetrated, the possibility of rectal injury should not be overlooked before relegating the case to a low priority on the operative schedule during a rush period.

It is as important not to overlook concomitant injuries as it is to search for rectal injury. The urinary tract is investigated by physical examination for urinary extravasation by catheterization and by urinalysis. It has been our policy to carry out this procedure in every case of injury about the pelvis. The possibility of peritoneal penetration and major vascular injury is the object of careful routine examination.

On the other hand, the presence of other apparently more urgent wounds should not be allowed to divert the attention of the examiner away from the possibility of rectal injury. Wounds with dominating symptoms which are most likely to coexist with penetrations of the rectum and thereby lead to incomplete investigation of a rectal injury are: (1) penetrations of the peritoneal cavity from wounds in the groins, hip area, sacral area, buttocks or posterior thighs; (2) wounds involving the urinary bladder or urethra; (3) wounds involving the major vessels of the upper thighs and pelvis; (4) wounds involving the sciatic nerve; (5) wounds involving the spinal cord; (6) wounds resulting in compound fractures of the pelvis, sacrum or femur.

Gordon Watson relates a bizarre experience with a patient with a bullet wound of the greater trochanter. A wound of the rectum was not suspected 'until the patient passed wind through the greater trochanter with a high musical note.

When a breach in the rectal mucosa is repeatedly contaminated from intraluminal contents the spread of infection takes place along fascial planes.

The fascia of the pelvis is reflected over the muscular structures and over the pelvic viscera so that it is commonly resolved into (a) the fascial sheaths of the obturator internus muscle, the piriformis and the pelvic diaphragm (b) the fascia associated with the pelvic viscera known as the endopelvic part of the pelvic fascia or simply as the endopelvic fascia (2).

The endopelvic fascia is reflected over the various pelvic viscera to form fibrous coverings for them. It is attached to the diaphragmatic part of the pelvic fascia along the tendinous arch and has been subdivided in accordance with the viscera to which it is related. Thus, its anterior part, known as the vesical layer forms the anterior and lateral ligaments of the bladder. Its middle part crosses the floor of the pelvis between the rectum and seminal vesicles as the rectovesical layer. Its posterior portion passes around the rectum forming for it a loose sheath which is however firmly attached around the anal canal. This sheath is known as the rectal layer of the endopelvic fascia. By common usage the name "fascia propria" of the rectum has been applied to this part of the endopelvic fascia. Actually it does not belong to the mural structures of the rectum but, as has been pointed out, is part of the endopelvic fascia covering this organ.

The abdominal counterpart of the endopelvic fascia is the endoabdominal fascia (transversalis fascia) which encases the abdominal cavity on all sides. In fact, the endopelvic and endoabdominal fascias fuse at the upper border of the obturator internus muscle and have been described as one and the same layer. Analogous to the layer of fat containing blood vessels (propentoneal fat retroperitoneal fat) which lies deep to the endoabdominal fascia, is the pelvic layer of fat containing blood vessels, which lies deep to the endopelvic fascia. In the pelvis, where peritoneum does not exist this layer of fat lies directly upon the pelvic viscera serving as a protective layer for the blood vessels nourishing these organs. The portion of this fatty layer which surrounds the bladder is known as prevesical fat. The portion which surrounds the rectum is less well known but can be clearly demonstrated, especially in well nourished young adults and can be termed prerectal or perirectal fat. The only barrier between the perirectal fat and the lumen of the rectum consists of the coats of rectum itself namely the longitudinal and circular mus-

Fig. 3 Diagram of coronal section of rectum showing mode of contamination of perirectal space from within and without. Width of perirectal space exaggerated.

cular coats the areolar coat (tela submucosa) which connects the muscular and mucous layers closely together and the mucous membrane.

With this anatomical picture in mind the path of bacterial invasion from the rectal lumen via a wound in the rectal wall is evident. Bacterial contamination from an active fecal current can pass through the injured rectal wall and attack the susceptible fat (Fig. 3). Without an adequate opening in the rectal portion of the endopelvic fascia this layer of fat is placed under pressure and rapidly breaks down. Since most penetrating wounds of the rectum have long tracts from the point of entry on the skin to the lumen the various layers of muscle and fascia of the buttock, thigh or back whichever the case may be slide to form trap doors at each tissue plane. Thus the escape of infected material is blocked even in cases in which the missile tears a gaping hole in the rectal layer of the endopelvic fascia. This situation can result in either a localized pelvic abscess or in pelvic cellulitis. The latter condition is due to the continued breakdown of fat through out the pelvis under the pressure of infection which follows the path of least resistance. Because of the connection between the endopelvic and endoabdominal fascias, it is actually possible for infection to continue upward in the retroperitoneal fat to produce a perinephric abscess.

Infection of the perirectal space can occur even in the absence of penetration of the rectum when this space is not adequately decompressed surgically after a missile enters its confines. It was possible for us to study this type of lesion in a patient who had suffered multiple severe shell fragment wounds which penetrated the thighs, legs, feet back, and buttocks with several compound fractures including that of one femur. This patient died 6 days after injury following the development of clostridial myositis (*Clostridium oedematiens*) of the thigh. The missile which penetrated the buttock passed through the

Fig. 4. Skin incision for parasacrococcygeal approach to incision of rectal portion of endopelvic fascia. Insert shows curved transverse incision below tip of coccyx as an alternate type of approach.

gluteal muscles and the sciatic notch penetrating the rectal portion of the endopelvic fascia, but spared the rectal wall. A sigmoid colostomy had been done because of confusion of the rectal mucosa, but the foreign body lying next to the rectum could not be removed nor could the perirectal space be decompressed because of the patient's desperate condition. The patient's postoperative condition never warranted a second operation to incise the perirectal fascia. This unfortunate situation afforded us, nevertheless, an opportunity to study the pathological consequences of contamination of the perirectal space from without uncomplicated by fecal contamination from within the rectal lumen as well as to observe the effects of inadequate decompression of the perirectal space. Postmortem examination of the tissue about the perirectal missile revealed a liquefaction necrosis of the perirectal fat extending for several centimeters around the missile which was a jagged piece of metal with a small piece of cloth. The rectal mucosa was intact and the missile plugged the tear in the fascia, thus allowing no escape for the enclosed space infection. Though this lesion was not responsible for the patient's death it could well have led to pelvic cellulitis or abscess formation. The routine administration of penicillin to this patient may have limited the spread of infection but only adequate surgical decompression of the perirectal space and removal of the foreign body could have allowed healing to take place.

The initial operative treatment of penetrating wounds of the rectum is designed to prevent this series of events by employment of the following procedures: (a) complete débridement of the tract; (b) adequate incision of the rectal portion of the endopelvic fascia (so called "fascia pro-

pria") with suture of the rectal wall when the defect is large; (c) construction of a temporary occlusive colostomy designed to divert completely the fecal current and to prevent recontamination of the wound from within. Some details of the technique employed in these procedures will be mentioned.

Removal of the coccyx does not, in itself, accomplish drainage of the perirectal space. Coccygectomy may or may not be a part of the operation, depending upon the individual case. Further, not only is coccygectomy unessential in most cases but it may actually contribute to certain postoperative complications.

In the early cases of our series we were performing coccygectomy almost routinely as a preliminary step to incision of the rectal portion of the endopelvic fascia. Surgeons in the base sector hospitals noticed instances of osteomyelitis of the sacrum and pain in the region of the coccygectomy in a few patients evacuated to them for secondary care (3). As far as we can determine, neither of these complications occurred in any of our cases. However, we agreed that not only could adequate drainage of the proper spaces be obtained without coccygectomy but that a longer incision could be made in the endopelvic fascia if the parasacrococcygeal incision was employed without coccygectomy (Fig. 4). Coccygectomy was reserved for those cases in which the foreign body actually fractured or partially destroyed the coccyx. When the sacrum was perforated the bony defect was débrided and the parasacrococcygeal incision made without coccygectomy.

In doing the parasacrococcygeal drainage, it is important to recognize the various anatomical layers as they are incised. After traversing the skin and subcutaneous fat the following layers can be recognized: superficial fascia, gluteus maximus muscle near its origin on the lateral aspects of the sacrum and coccyx, the thick, white fibers of the fused heavy ligaments (consisting of the superficial posterior sacrococcygeal ligament, the sacrotuberous ligament and the short posterior sacrolumbar ligament), loose areolar tissue, the relatively thin rectal portion of the endopelvic fascia.

With a finger in the rectum, the rectal portion of the endopelvic fascia is incised, thus exposing a thin fatty layer (perirectal fat). This fat may be blood stained and not easily recognizable but with careful dissection is unmistakable. In some instances the rectal finger may stretch the mural structures excessively, giving the surgeon the impression that the fascia must certainly have been

traversed because of the thinness of the tissues drawn over the finger. If the fatty layer is not identified the proper fascia has not been incised or the fatty layer has not been recognized. The incision in the rectal portion of the endopelvic fascia can be carried the entire length of the skin incision. Since the incision does not involve mural musculature of the rectum or anus, there is no reason to fear incision of the internal sphincter.

The incision described is done on the side of the penetration into the rectum. If there are two perforations it is done on the side having the larger defect. It need not be done on both sides. If the opening into the rectum is large and can be readily found it is closed with either interrupted sutures or a continuous suture of silk, bringing mucosa to mucosa. If the defect cannot readily be seen and proctoscopy has shown it to be small it need not be sutured since the contraction of the mural fibers in bowel at rest will permit the edges to meet and seal.

In the opinion of some surgeons, adequate drainage can be secured through a transverse curved incision inferior to the tip of the coccyx incision of the rectal portion of the endopelvic fascia and opening of the perirectal space by blunt dissection (Fig. 4). This technique was not employed in any of our cases.

When coccygectomy is indicated it is important to do a complete excision. To leave the proximal segment of the coccyx or a portion thereof usually results in pain on sitting as a late complication. Excision of the coccyx is done with a scalpel. As a rule no bone cutting instrument need be employed. The coccyx is disarticulated at the sacrococcygeal joint and the remaining cartilage on the articular surface of the sacrum is removed with a curette. If cartilage is allowed to remain it may become necrotic. Extensive partial sacrumectomy is probably an unnecessary procedure in most cases. If the wound has perforated the sacrum it is only necessary to remove contaminated and devitalized bone by curettement. If the posterior opening into the rectum is large and lies under the sacrum it can be sutured through the parasacrococcygeal incision without destroying a large portion of the sacrum for this purpose.

There is no need to discuss in detail the débridement of the soft tissue wound. Suffice it to say that this should be thorough with provision made for adequate drainage by generous incision of fascia.

The posterior portion of the operation (débridement and decompression) is best done before the

colostomy is made since it is preferable to complete the operation with the patient lying upon his back. It is well known that turning a patient toward the end of a time-consuming operation has a more profound effect on the patient's blood pressure than if he is turned early in the procedure. Furthermore, by doing the posterior portion of the operation first, it need not be rushed as it might be if done as a last minute procedure with the patient's blood pressure dropping. The only instance in which the abdominal portion of the operation is done first is in the case of active intra-abdominal hemorrhage.

The abdominal incision employed in cases requiring colostomy is usually a right paramedian incision. This incision allows somewhat more room for the occlusive dressings which separate the incision from the left iliac colostomy than would an incision on the left side of the midline.

It is not within the scope of this paper to describe the operative treatment of intra-abdominal penetrations, other than to state that a routine inspection of the intraperitoneal viscera is made and all visceral perforations closed including the perforation in the peritoneum caused by the missile, before the colostomy is made. It might be mentioned that perforations in the anterior intraperitoneal wall of the rectum usually bleed profusely and may be the only source of bleeding in a patient in severe shock due to intraperitoneal hemorrhage.

The usual site for the temporary colostomy in cases of rectal injury is the sigmoid colon. However, if any portion of the transverse or descending colon has been perforated by a concomitant injury, exteriorization of this portion of the bowel can be employed as the site for temporary colostomy. When the right colon or cecum is perforated as well as the rectum, it is advisable to perform a sigmoid colostomy in addition to whatever procedure is carried out on the right colon.

In instances of severe destruction of the rectum which will require extensive reconstruction at some future time, it is best to perform the colostomy in the transverse colon with the two stomata completely separated by a bridge of skin. The surgeon doing the reconstructive surgery will then be able to mobilize sigmoid colon downward, if necessary for the repair of the defect.

Our decision as to which type of sigmoid colostomy to perform—spur or loop—has been governed largely by the expressed preference of the surgeons in the base sector to whom our cases were evacuated. Some preferred to close the colostomies by crushing a long spur; others claimed it was easier to suture the loop colostomy.

and return it to the abdomen. In a recent comparative study it was found that the percentage of successful closures was about the same in both types. The problem thus resolves itself to one of individual preference of the surgeon doing the closure. Regardless of which type is done its main purpose is to divert the fecal current. It must place the rectum at rest by preventing any newly formed feces from being packed into the rectum. Stretching of the wall of the rectum can cause contamination of the perirectal tissues by the seepage of material through the wound in the wall.

The technique of enostomy will not be entered into in detail here since the salient features have been emphasized repeatedly in the literature. The usual precautions of mobilizing sufficient colon to permit a generous portion of exteriorized bowel to protrude without tension, were followed in our series. The left iliac muscle-splitting incision was placed as far lateralward as possible. When indicated, the lateral peritoneal gutter was obliterated by tacking the colon to the peritoneum.

Most of our colostomies were opened immediately after operation and a Paul tube placed into the proximal loop. This was removed after 24 hours. All loop colostomies were treated in this manner. In some instances of spur colostomy the bowel was clamped at the time of operation, and the proximal loop opened 24 hours after operation for the insertion of a catheter. In such cases the catheter was removed after an additional 24 hours, and the bowel was divided at the site of the clamp.

In no case was lavage of the distal loop carried out on the premise that whatever fecal material remained in the distal loop soon became dehydrated and stationary and might even serve as a "splint" around which the rectal wall could be immobilized, thus permitting healing to progress unimpeded. It is our impression that reinfection comes from new moist fecal material and from activity of the rectal wall rather than from inspissated, dehydrated contents.

Some mention should be made of the preoperative and postoperative care of these patients. All patients who were suspected of having an injury of the rectum were given the same operative priority as were patients with penetrating wounds of the abdomen; they were placed in the shock ward where they could get closer attention than in the preoperative wards during a large influx of patients. Here they were carefully examined and a record was made of temperature, pulse, respiratory rate and blood pressure. Patients with penetrating wounds of the rectum

were typed and their blood cross-matched for blood transfusion. If the patient was in good condition this procedure was nevertheless carried out so that blood would be available and ready at the time of operation. Patients in shock received an emergency transfusion of 500 cubic centimeters of low titer type O blood from our blood bank together with 200 cubic centimeters of a 2 per cent solution of sodium bicarbonate intravenously while their blood was being cross-matched for further transfusions. Most patients had received infusions of plasma at the battalion aid station or regimental aid station. Those in good condition were usually somewhat dehydrated on admission to our hospital. Such patients received an intravenous infusion of 1000 cubic centimeters of 5 per cent dextrose in normal physiological solution of sodium chloride, or in water slowly. Roentgenograms were taken after the systolic blood pressure stabilized over 100 millimeters of mercury. A urine specimen was obtained from each patient, by catheterization if necessary and an immediate urinalysis was done. Chemotherapy was instituted on admission of all patients. Early in our series, this consisted of administering 2.5 grams of sodium sulfadiazine dissolved in the intravenous solution preoperatively. Postoperatively 5 grams of sodium sulfadiazine was given daily in two divided doses 12 hours apart dissolved in the intravenous solutions until the patient could take the drug by mouth. He was then given 1 gram of sulfadiazine with 4 grams of sodium bicarbonate every 4 hours. Daily urinalyses were checked for sulfadiazine crystals, pH, and microscopic hematuria. Records were kept of fluid intake and output. Since May 1944, all patients received intramuscular injections of penicillin, 25,000 units every 3 hours, beginning on admission and continuing until the patients were well along in their postoperative course. A Levin tube was inserted into the stomach of patients suspected of having penetrating wounds of the abdomen.

Every patient operated on for a penetrating wound of the rectum received a blood transfusion during the operation, in amounts varying from 500 to 2000 cubic centimeters, depending on the requirements. Endotracheal gas-oxygen-ether anesthesia was used in all cases.

The postoperative management depended to a considerable extent upon the nature of the concomitant injuries. For example, those patients with penetrations of intraperitoneal viscera were treated with Wangenstein suction, intravenous therapy and parenteral vitamins for approximately 4 days. Those patients whose only vis-

eral wound was one of the rectum were allowed to have fluids by mouth beginning 24 hours after operation. Within 72 hours, their diet was usually converted to a dry diet to prevent a loose irritating stool at the colostomy.

The patients were kept at our hospital for a postoperative period ranging from 9 to 15 days, and were not evacuated to the base until they were in good condition.

ANALYSIS OF CASES

The interval between the time of wounding and the time of operation averaged 21 hours in our series, the extremes being 8 hours for the shortest time interval and 55 hours for the longest. Most of the long interval cases resulted from delay in evacuation in the mountainous terrain of the Casimo campaign in the winter of 1943-44. During this campaign most of the wounded had to undergo a dangerous time-consuming trip being first carried by shuttles of litter bearers down icy treacherous mountain trails often followed by a further trip by mule pack, and finally a long ride in an ambulance which had to pick its way along rough partially destroyed mountain roads. Although the terrain was even worse in the winter campaign of 1944-45 the casualties reached us in a shorter time because of ingenious improvements in methods of evacuation from the mountains, such as ski-litters and cable baskets. Once the patients reached our evacuation hospital the average time between admission and operation was $4\frac{1}{2}$ hours for our series of rectal injuries. Generally 2 hours was the minimal time necessary for resuscitation, examination, roentgenography and preoperative preparation.

The location of the wounds of entrance in our cases is worth noting. In 4 cases the wound of entrance was in the thigh. One of these had caused a compound fracture of the femur. In 3 cases the wound was in the hip area, and in one case it was above the iliac crest. These data lend importance to the warning that the rectum may be perforated in instances in which the wound of entrance is remote. In 9 cases the missile caused a compound fracture of the sacrum, coccyx or pelvic bones. Six of these entered through the sacrum. Eighteen wounds of the rectum were the result of wounds of the buttocks (Fig. 5).

In 21 instances, multiple wounds were present. Of these, 7 had penetrated intraperitoneal viscera, while in 2 patients the urinary bladder was perforated. Ten patients had concomitant wounds of extremities. Of these 2 involved major vessels, 1 the sciatic nerve, and there were 5 compound fractures of the extremities. Two patients had

Fig. 5 Diagram showing location of wounds of entry of missiles which penetrated or perforated the rectum in series of 35 consecutive cases. This emphasizes the fact that wounds of entry may be remote.

thoracoabdominal wounds. It is these cases of multiple injuries which tax the endurance of the surgeon and which require painstaking clinical evaluation before surgery as well as diligent after-care.

Postoperative complications occurred in 5 cases. In 2 instances secondary hemorrhage from the middle sacral artery occurred, one 6 days after operation and one 8 days after operation. Both of these patients had had coccygectomies. The hemorrhage was arrested in both cases and blood volume was restored. Both had uneventful courses thereafter up to the time of evacuation 15 and 14 days postoperatively respectively.

In the other 3 cases, the complications led to death of the patient, although in only 1 case did the complications result from the rectal wound. These 3 cases constitute the total mortality in our series of rectal wounds, and represent 8.5 per cent of the series. In 1 case abstracted previously in this paper the rectum was contused but not penetrated although the missile entered the perirectal space. As stated this patient died as a result of clostridial myositis of the thigh muscles following severe penetrating wounds of this part and a compound fracture of the femur.

In the second case death was due to extensive damage to the parenchyma of both lungs and severe shock. The patient suffered multiple wounds of the back, one of which perforated the sacrum and penetrated the rectum. In the right chest there were comminuted fractures of the 7th and 8th ribs with laceration of the pleura, penetration of the right lower lobe with extensive interstitial hemorrhage and hemothorax. The missile which entered the left chest caused com-

minuted fractures of the 10th and 11th ribs, laceration of the pleura, hemothorax, severe interstitial hemorrhage of the left lower lobe, perforation of the diaphragm and laceration of the spleen. Besides these wounds, there were multiple penetrating wounds of the legs, arms, neck, and scalp, and a compound comminuted fracture of one foot. The right kidney was contused and there were cortical hemorrhages in both suprarenal glands. The patient was admitted 6 hours after injury in profound shock. Desperate efforts were made to treat the shock, but response was poor. Operation was undertaken on the basis of continued intra-abdominal hemorrhage. Through a laparotomy incision a splenectomy was done and a large tear in the left diaphragm was sutured. A sigmoid colostomy was brought out through a left iliac muscle-splitting incision. The penetrating wounds of the chest were debrided and the deep layer was closed. Thoracostomies were done, and all wounds were debrided. The perirectal space was drained. Although the patient rallied immediately after operation he never did fully recover from the state of shock, and died on the first postoperative day. In this case the rectal injury was of secondary importance and can hardly be implicated as a cause of death.

The third case illustrates the spread of infection along the anatomical planes described earlier in this paper. The patient reached our hospital 38 hours after injury during the *Casino campaign*. He was in severe shock, but responded to the usual treatment of massive blood transfusions and supportive measures. He had multiple wounds of the buttock, thigh and leg with evidence of a gas-producing clostridial infection of the thigh wound. There were two perforations of the extraperitoneal portion of the rectum; the patient's abdomen was rigid, and there were diminished peristaltic sounds. At laparotomy no visceral perforations were seen but about 2 ounces of turbid fluid was found in the lower peritoneal cavity. A small area of necrosis was noted on the anterolateral portion of the rectum at the peritoneal reflection. Gas was discernible in the retroperitoneal region over the left iliopectus muscle. Definite crepitus was noted with digital pressure on the posterior peritoneum in this region. A sigmoid colostomy was made. Colecystectomy with drainage of the perirectal space was done and the wounds of the extremities were debrided radically. There was no major vascular damage in the thigh but the muscle damage was extensive and showed signs of clostridial myositis. Despite all efforts, including antitoxins, penicillin and blood transfusions, the patient de-

veloped a severe toxemia and died 4 days after operation.

At postmortem the diagnosis of a clostridial gas-producing infection of the thigh was confirmed. Regarding the rectal lesion and the gas in the retroperitoneal space, the following excerpt from the autopsy protocol¹ is of interest.

On the anterolateral aspect of the lowermost portion of the intraperitoneal rectum at the peritoneal reflection is an irregular, patchy gray area of necrosis measuring 7 by 4 centimeters. This is on the right side. Dissection of the perirectal tissues reveals two tracts passing from the left obturator canal into the substance of the rectal wall here they perforate the mucosa of the rectum 6 centimeters apart, the highest at the level of the peritoneal reflection. These perforations are on the posterolateral aspect of the rectum on the right. The margins of the mucosal openings are ragged and gray and no foreign body can be located in the rectum or rectal wall. The pararectal tissues along the tracts and the perirectal fat at a distance from them exhibit a grayish green gelatinous edema and necrosis with no localization of purulent material. This edema extends to the brim of the pelvis posteriorly, but there is no evidence of gas-producing infection here. It is likely in view of the findings in the perirectal tissues that the gas encountered in this region was derived from the lacerations in the rectal wall, and not from the infection in the thigh, since there is no direct connection between the two areas of infection.

In this case the spread of infection under the endopelvic fascia had already taken place before the patient came to surgery. Whether the posterior decompression and colostomy ordinarily preventive measures, might have been successful as therapeutic measures in the presence of an already established infection, had the gas infection of the thigh not caused the patient's death, remains an unanswered question. This case illustrates the consequences of a long time lag before surgery in certain instances. However there were several other cases in our series with even longer time lags in which recovery followed initial surgery. This was the only instance in the series in which a spreading pelvic infection was seen.

FOLLOW UP

Since patients with rectal injuries did not leave our hospital until they were in good condition, there was little reason to expect infection to occur at a subsequent date. However questionnaires were sent out to base sector hospitals asking for follow up information on those patients which the author could not visit at the base. Information was obtained in 21 of our 35 cases, giving us a representative cross section of the disposition of the cases.

The follow-up covered an average period of 67 days after the patients left our hospital. Contact

Postmortem examinations were performed by Major Leo Kaplan, M.C. A.U.K.

was lost once the patients were sent to the zone of interior but all such patients were sent out in good condition. Of 21 patients on whom follow-up was possible there were no deaths. Colostomies were closed in the overseas theater in 13 instances. Of these patients 2 were returned to limited overseas duty while 11 were sent to the zone of interior. Some patients who might otherwise have had closure of colostomies overseas, were sent to the States without closure because of the severity of concomitant injuries or for reasons of general expediency. It is difficult, therefore, to estimate what percentage of patients with injuries of the rectum can be expected to return to limited overseas duty. Since there were no complications in any of the cases in which follow up was possible and since those who were sent to the States left the overseas base sector in good condition we can also feel justified in expecting a satisfactory recovery as far as the rectal injury is concerned, in most patients whose colostomies were not closed overseas.

DISCUSSION

The notable absence of complications due to infection in the follow up period of our series, and the almost complete absence of pelvic cellulitis (except in one case, in which this was present before surgery) bring up several questions pertinent to the initial surgical management in cases of rectal wounds. How many of these patients would have developed complications if the surgery had been less radical? Was colostomy necessary in every case? What about those cases in which posterior decompression was obviously inadequate, and which nevertheless had an uneventful course? What rôle did chemotherapy play in the outcome of these cases? What was the course of those patients in whom a rectal injury was not discovered?

Certainly the answers to these questions cannot be found in an analysis of our limited series. Perhaps, at some future date, after reports are compiled from theaters of operation throughout the world, it will become possible to state criteria on which to base the selection of cases of rectal injury for radical initial surgery. However some parts of these questions can be clarified from our experience.

We have felt safer in attempting to decompress the perirectal space and in diverting the fecal stream at the initial operation since it was necessary to evacuate the patients to rearward areas after approximately 10 days. The patients passed through the hands of several surgeons at various institutions, and it was impossible for

the original surgeon to follow each case to its conclusion. It was, therefore in all probability a safer procedure to design the initial surgery to prevent exigencies which might otherwise arise. In civilian practice, many of our patients might have been carried along under close observation until it could be definitely determined whether or not a colostomy should be performed.

Those patients in whom posterior decompression was obviously inadequate, but who nevertheless had uneventful courses probably had drainage through the opening caused by the missile. Surgeons at the base sector hospitals have observed an occasional case of pelvic abscess developing late but this complication was rare, and as far as we can determine, did not occur in any of our cases.

The exact rôle of chemotherapy in cases of rectal injury is unknown. There has been no noticeable difference in the course of our patients treated with sulfonamides and those treated with penicillin, despite the fact that penicillin has no effect on bacteria of the colon group. It is our impression that the initial surgery was the main feature in the treatment, with chemotherapy serving as an adjunctive control of infection.

As to the course of patients in whom treatment was delayed or in which a rectal injury went undiscovered we have two opposite types of cases to cite. One had an extremely rapid spread of pelvic infection within 38 hours while the second developed no ill effects whatever up to 8 days following rectal injury. The first case already abstracted was one in which the patient developed an extensive pelvic and retroperitoneal infection within 38 hours after injury before surgery was undertaken. As stated this patient died from a toxemia and clostridial infection of a thigh wound so that clear cut evidence of the effects of the pelvic infection could not be appraised. It is known however that this type of case carries a high mortality rate. In the last war for example pelvic cellulitis from rectal wounds resulted in a fatal issue in 45 per cent of cases (4). For purposes of illustration this case represents the rapid spread of pelvic infection from a rectal wound despite the use of prophylactic penicillin therapy.

By contrast, is the case of a patient with a perforation of the rectum who reached our hospital 6 days following injury without surgical treatment. He was a German soldier who was admitted from a German *Feld Lazarett* during the overwhelming influx of prisoner patients shortly after the mass surrender of the enemy in northern Italy. His wound was a transversely perforating gunshot wound entering the left trochanteric area and

emerging in a similar area on the opposite side. The only treatment he had received in the 6 days since wounding was an occasional dose of a German sulfonamide. The patient stated that he had had a few bloody stools for one or two days following injury but bowel movements had been normal since then. There were no fractures or signs of vascular injury. Proctoscopic examination revealed a laceration about 1 centimeter long in the posterior portion of the rectal mucosa 5 centimeters from the anus. The wound contained a bit of clotted blood and the surrounding mucosa appeared normal. There was no evidence of perirectal abscess. The external wounds were clean and dry. Temperature, pulse, and respirations were normal. In view of the patient's excellent condition and the 6 day interval since wounding, it was decided that a conservative policy be followed. Hence no surgery was done by us and the patient was placed on penicillin therapy and watched. He was followed for a period of 3 days at our hospital during which time he had no elevation in temperature, nor was he particularly uncomfortable. He was evacuated as a litter patient in good condition to a rearward installation.

This case illustrates the fact that there are some cases of rectal injury in which major surgery is not necessary for the recovery of the patient. But what criteria can the surgeon rely upon to determine in which cases of rectal injury major surgery will be required and in which ones it will not? Plainly there are no such criteria available at the present time. This fact has been largely responsible for our policy of performing a colostomy and decompressing the perirectal space in all cases of wartime injuries of the rectum. The results of this surgical policy have been most encouraging and have brought about a remarkable reduction in both mortality and morbidity as compared with previous statistics. Until new criteria can be established for proper selection of cases for nonintervention we believe that we should rely upon these surgical measures as insurance factors in all wartime injuries of the rectum.

SUMMARY

Experiences and results in the initial surgical management of 35 consecutive cases of battle injuries of the extraperitoneal portion of the rectum are reviewed. Important aspects of the diagnosis of such cases are presented. Rectal injuries in wartime are usually associated with multiple injuries of other structures, and it is important that the rectal injury not be minimized or overshadowed by the presence of other apparently more serious wounds at the time of initial examination. The anatomical relationships of the endopelvic fascia are reviewed to emphasize the purposes and aims which initial surgery must accomplish in order to prevent pelvic infection. The two main features of the initial surgery are (1) decompression of the perirectal space by adequate incision of the rectal portion of the endopelvic fascia (so-called "fascia propria") and (2) colostomy to divert the fecal current until the wound is healed. The surgical technique is described. During a follow-up period averaging 67 days in 21 cases, there was a remarkable absence of complications from infection. Certain questions pertaining to the care of rectal injuries remain unanswered, such as the rôle of chemotherapy and the selection of cases for nonintervention. The policy which we have followed and which is, in our opinion, the safest under conditions of warfare consists of surgical intervention as described herein, supplemented by chemotherapy in all cases of penetrating wounds of the rectum.

THE USE OF CURARE IN ANESTHESIA FOR THORACIC SURGERY

Preliminary Report

PHYLLIS HARROUN M.D., and HUBERT R. HATHAWAY M.D. San Francisco, California

MOST thoracic surgeons in this area agree that the optimum operating conditions for intrathoracic disease, and also the least physiological upset to the patient, are afforded by the so-called "apneic technique" of anesthesia the patient's lungs being intermittently inflated by gentle pressure on the breathing bag. However this procedure necessitates the use of potent anesthetic agents, all of which with the single exception of chloroform, are explosive, thus contraindicating the use of the cautery once the pleura is opened. Most anesthetists consider chloroform too toxic a drug to use over the long periods required for intrathoracic surgery.

Although spinal analgesia permits the use of the cautery inside the chest in cases of thoracic surgery few anesthesiologists have availed themselves of this method as a means of producing apnea. Therefore, in our opinion controlled respiration cannot be used satisfactorily in these cases.

When curare was first utilized as a relaxing agent in anesthesia for abdominal surgery it was claimed that its danger lay in its faculty of producing respiratory depression which might even proceed to apnea if unduly large doses were used. As a result of this statement, we conceived the idea of using this property of curare for the production of apnea during intrathoracic operations. If this proved practical nonexplosive nitrous oxide could be utilized as the anesthetic agent and the surgeon could use the cautery inside the chest.

To date this technique has been used on 11 patients undergoing intrathoracic operations in this hospital. The cautery has been used within the pleura in every case. It has proved easy to produce apnea and control breathing and no difficulty has been encountered in any case in persuading the patient to resume spontaneous respiration. The use of prostigmin for this purpose has not been found necessary. The patient's general condition during the operation and post-operative course has been excellent in all cases.

The only complications which could be even remotely attributed to curare are 3 instances of postoperative atelectasis. These may be attributed to the type of operation and the result of the medication.

TECHNIQUE

On the morning of operation, the patient is heavily medicated with a short acting barbiturate morphine and scopolamine, so that he will be brought to the operating room just sufficiently awake to move from bed to table. A nitrous oxide and oxygen mixture is administered by means of a face mask. If any difficulty is encountered in producing anesthesia smoothly enough sodium pentothal is injected intravenously to attain satisfactory anesthesia. (Pentothal is rarely necessary.) During induction particular notice is taken of the proportion of nitrous oxide and oxygen necessary to keep the patient in first plane anesthesia and well oxygenated. A pharyngeal airway is inserted and the anesthetist's ability to inflate the lungs by pressure on the breathing bag is tested. We consider it unwise to administer curare unless a perfectly free airway allowing inflation of the lungs exists. A quantity of curare¹ calculated to be sufficient to stop spontaneous respiration is then injected intravenously. No particular precautions about speed of injection are taken. This first administration usually amounts to 150 to 200 milligrams of curare. Complete apnea or at least profound respiratory depression usually follows in from 30 seconds to 2 minutes. The patient's lungs are then inflated by gentle intermittent pressure on the breathing bag. After approximately 5 minutes, when the maximum relaxation has been attained the mask is removed and an orotracheal tube with an inflatable cuff is inserted under direct vision. The profound muscular relaxation usually makes intubation an easy matter. This tube is connected to a canister of soda lime and a breathing bag; the delivery tube from the anesthesia apparatus is attached and anesthesia is continued the same concentration of nitrous oxide and oxygen being used which was previously found to keep the

REORGANIZATION OF THE SURGICAL PUBLISHING COMPANY OF CHICAGO

IN accordance with the terms of the will of Dr Franklin H. Martin all shares of stock of The Surgical Publishing Company of Chicago at his death became the property of the American College of Surgeons subject to a life interest in the company in favor of Mrs. Isabelle Hollister Martin, his widow. Following her death, the management of The Surgical Publishing Company of Chicago which publishes SURGERY GYNECOLOGY AND OBSTETRICS thus has become the responsibility solely of the American College of Surgeons.

The Board of Regents of the American College of Surgeons has elected a Board of Directors for The Surgical Publishing Company an Executive Committee of the Board of Directors, and an Editorial Policy Committee.

The Board of Directors for the Surgical Publishing Company consists of the following

Dr Irvin Abell *Chairman*
Dr Arthur W. Allen
Dr Donald C. Balfour
Dr Frederick A. Collier
Dr Harry S. Gradle
Dr Howard C. Naffziger
Dr Dallas B. Phemister

The Executive Committee of the Board of Directors consists of the following

Dr Dallas B. Phemister *Chairman*
Dr Frederick A. Collier
Dr Howard C. Naffziger

The Editorial Policy Committee consists of the following

Dr Donald C. Balfour *Chairman*

VENOUS THROMBOSIS AND PULMONARY EMBOLISM

SUDDEN death during convalescence has always been a most disturbing episode. Lay people have learned to dread it and doctors have long been depressed by this insidious and unexpected interference with the recovery of their patient. Massive pulmonary embolism from the leg veins is the most common source of this catastrophe. In the middle twenties reports from large clinics showed that three persons in each 1000 subjected to surgery would die during convalescence from this cause. Much was done to prevent these deaths and by careful attention to frequent change in posture and efforts directed to diminish stasis in the leg veins, the ratio of fatalities from embolism was reduced to approximately 1 in 800. All this did not take into account the prolonged convalescence brought about by thrombophlebitis with the post

phlebotic edema and subsequent leg ulcers so frequently seen in those who recovered

Various studies directed toward this problem by many minds finally have brought about certain facts that are important. The development of bland thrombi in the leg veins that come about with no warning has been a new line of thought in recent years. Homans of Boston and Ochsner of New Orleans have contributed much to this subject. The former has preferred the term 'bland thrombosis' and the latter that of 'phlebothrombosis'. These men have emphasized the importance of thrombosis that is noninflammatory and due to the lack of reaction in and about the vein. There is far greater chance of such a thrombus leaving the vein and being deposited in the lung. If small, this detached thrombus produces an infarct or if massive enough it may completely occlude the pulmonary artery producing death within a few minutes. This is a different type of thrombosis than occurs in thrombophlebitis. In this latter disturbance of the venous return there is an inflammatory reaction that produces the painful swollen extremity known as phlegmasia alba dolens. That infarct or fatal embolism is less common in this type of thrombosis is an established fact. This is doubtless due to the firm attachment of the clot to the wall of the vein present in this type of inflammatory thrombosis. We have found that phlebothrombosis will often and in a higher proportion of cases in certain climates become thrombophlebitis.

Efforts to prevent serious sequela from thrombosis of the leg veins have led us to seek methods to prevent the thrombosis in the first place and if thrombosis occurs to prevent death from massive embolism and now to diminish the convalescence of such a victim even though a fatal embolus might be unlikely.

Anticoagulant drugs administered first after the thrombosis had become established came

into vogue with the discovery and use of heparin. This method gave excellent results in many cases but due to the difficulties arising out of its use it is now more generally relied upon as the adjunct to other forms of treatment. This drug could hardly be used routinely as a preventative unless the newer intramuscular type of heparin in-oil proves to be innocuous, inexpensive and reliable. Dicumarol seems to be satisfactory in the hands of experts as a preventative of serious thrombosis and has the advantage of oral administration and a low cost. However it carries the absolute necessity for accurate laboratory control of the prothrombin level and if great care is not exerted the complications may outweigh its benefits. Serious hemorrhage that has proved fatal in some instances has occurred following its use. In all probability further study and research along the lines suggested by the effects of heparin and dicumarol will eventually bring about a safe and satisfactory use of these or similar acting drugs.

Over ten years ago Homans reported four instances of femoral vein interruption in patients who were having repeated infarcts from bland thrombosis. Due to the immensity of the problem in the Massachusetts General Hospital there has come about a gradual but steady trend toward femoral vein interruption as an answer to this question. To August 1, 1945, 861 patients in this institution have been subjected to femoral vein interruption. At first attempts were made to determine whether or not a thrombus existed by phlebography—now this method has been abandoned. Early we learned that the apparent sick leg might be misleading and that often the most dangerous thrombosis was lying dormant in the opposite, apparently normal side. Therefore we have gradually become convinced that bilateral interruption should be done. Much time, thought, and discussion

have entered into the subject regarding the site of interruption. Vena cava ligations have been carried out successfully by Linton in 14 instances. He is disturbed that two of these patients have developed postphlebitic edema with ulcer. Iliac interruptions have been sponsored by Homans who felt that this more serious undertaking was justifiable in order to get above the clot and because the collateral circulation was better at that level than it was after femoral vein interruption. Common femoral vein interruption has been done in a considerable number of our cases but we realize that the technical hazard is greater and that actually a serious acute edema can follow this procedure under certain circumstances. The majority of our patients have been subjected to interruption of the femoral vein distal to the profunda femoris. This permits an easy exposure of a segment of vein without branches to allow opening of the vein and the removal of thrombi proximally and distally by suction and final complete division of the vein.

In this series there has been no fatality as a result of the procedure. There have been surprisingly few instances of infection or lymphorrhea. Only one of the patients has developed a postphlebitic ulcer. The average hospital stay after femoral vein interruption has been about six days. Patients operated upon before leg swelling develops have no postoperative edema worthy of note. If the operation is undertaken after bland thrombosis has become inflammatory with pain and swelling then a period of postoperative edema occurs. This edema may last several months depending on the duration of the thrombophlebitis

before and after vein interruption. Approximately 6 per cent of the patients having had infarcts before operation will continue to have infarcts afterward. These may be serious enough to warrant the use of anticoagulant drugs. In one instance only was there a fatal embolism arising from the profunda femoris after superficial femoral vein interruption—this in a seventy-four year old man with widespread carcinoma arising from the stomach. He had evidence of thromboembolic disease on admission with immediate femoral vein interruption. His death occurred 8 days later.

This operation is so safe and so simple and if done on the normal vein produces so little swelling of the extremity that prophylactic vein interruptions are being done with greater frequency. Up to the date of this writing this procedure has been carried out in approximately 100 patients in our clinic. All of this group have been elderly patients who for reason of their acute disorders, would need a prolonged period of bed rest. Typical of these are the aged with fractures of the hip region.

Control experiments are being carried out on a group of patients between the ages of 40 and 65 with dicumarol after operation. The results of this study may show that fewer femoral vein interruptions may be necessary in certain types of patients. We feel at this time that older individuals may be more safely managed by prophylactic femoral vein occlusion. Fatal embolism is so much less likely under the age of forty that signs and symptoms can be relied upon to determine the need of thrombectomy and venous interruption in younger patients.

ARTHUR W. ALLEN

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

PERHAPS the most significant book that has emerged from the medical aspects of this war is Grinker and Spiegel's *Men Under Stress*. Not only is it an important book, but also an interesting one for it deals with a vital subject associated with war in an interesting personal way. The two authors have put themselves into this book with enthusiastic competence. This gives to its many pages the elements of unusual industry, personal knowledge, experiences gained from combat observation and from close contact with every feature of the aviator's job and the weapons he is trained to use. There is technical information about these things which is unusual in most medical contributions which have come out of this war.

The case reports are fine examples of clinical reporting. They are generally brief and to the point, centering about and presenting the clinical symptoms while illustrating the significant situations producing the psychiatric picture. They contain relevant material for explanation, interpretation, and therapy. There are 65 of these case histories, which is perhaps too many and make the authors seemingly overzealous to furnish proof of their ideas. The evidence is overweighted by this accumulation of data. This encourages repetition so that the book spins itself out to too great length.

Through the protocols of the soldiers with their neuroses and the discussions which follow the core of the authors' theory of the neuroses which is built around anxiety and the struggles of the ego and superego is nailed down.

The average reader will be so impressed with the mass of case material and the theories derived from them that he will have little doubt of their absolute validity. The critical reader on the other hand may be doubtful of the validity of any absolute statements about the human personality, especially when these statements concern the dislocation of the personality in the neuroses as substitutions of its pre-existing form.

In attempting to evaluate medical contributions which are written about this war it is well to keep in mind the essential and necessary weakness of all war books written during it. This is especially true of those dealing with the medical aspects of war for the atmosphere of war is not conducive to that critical restraint which is essential during peacetime writing on the same subject. A study of the very large number of papers on the war neuroses published during and after the first World War will

show the necessity for a critical examination of this book. The conclusions of its authors should not be regarded as final and absolute, despite their evident wish to have them so regarded.

There is little evidence of the necessarily tentative nature of our present day thinking on the subject covered by this book. A too ready acceptance of the meaning and interpretation of the war neuroses is not an advantage at the present time but, it seems inevitable if this book is taken as the final answer. Neither the sincerity nor the competence of the authors can be questioned. Their therapeutic planning, the execution of the plans and their successful management of individual cases are also not questioned. The total conception of the war neuroses, as brought out in this book, however cannot be accepted without a weighing of evidence and the critical analysis of the key implications of the personality structure of the aviator with war neurosis. If the authors' theories are accepted as fact, what is true for him is true for every man whether his neurosis be of war or civilian origin.

The authors' approach to the war neuroses is what may be called disguised Freudian. The psychoanalytic formulae are everywhere apparent, but seldom mentioned as such. This fact is disarming. The reader will find much to his surprise, that he has been reading about the war neuroses from the point of view of psychoanalysis. The adaptations of the Freudian concepts of personality structure, anxiety, regression, identification, childhood experiences, the pain-pleasure principle, infantile trauma and so forth, to the neuroses of war are slipped in without any warning to the reader. He will be disarmed further by the omission, in great part of the sexual implications in most of these and other concepts which are so deftly used to build up a body of Freudian doctrine which is nowhere acknowledged as such. Freud is not mentioned in the body of the book, nor in its preface. It is as though the authors planned it that way so as not to arouse opposition or prejudice against the theories that bear the burden of psychoanalytic thought. As understandable as this is in the broad scheme underlying this book, the innumeration of the Freudian view and the use of Freudian hypotheses demand critical scrutiny because apart from the descriptions and clinical reports this book gives a broadly conceived and convenient demonstration of the concepts of the Freudian psychology as the definitive and final interpretation of the war neuroses.

Prime importance is given to anxiety both as an affective state in itself and as an affective state with

demonstrable objective symptoms as well as various combinations of both. From all these conditions mental and emotional turmoil result. The articulate, descriptive ability is more evident in those instances in which objective symptomatic displays are less impressive. The authors use case histories to interpret and elucidate first, the eternal struggle between the ego and the superego second the regressive drives as necessary accompaniment of the neuroses and third, the enmeshing, constantly present anxiety. Anxiety works effectively chiefly through the autonomic system, plus the important rôle played by the endocrine structures as an adjunct source of symptoms.

It may well be that at the present time, there is no more adequate scheme of understanding the neuroses than the one used by the authors. It may well be that they believe their use of Freudian hypotheses as applied to such an array of cases is convincing proof of their validity. By continued use and repetition the authors theories assume the aspect of truth rather than remain a series of psychological hypotheses and speculations. Thus these in the conceptions of the authors become absolutes. There is scarcely a page in which the ego and the superego regression and anxiety are not mentioned. These concepts or working hypotheses become in the reader's mind established facts. They stand out, therefore as sharply fixed as those facts which are experimentally derived in physics or chemistry or any science which depends, for validity upon controlled experiments. But, despite repetition these concepts remain working hypotheses and are by no means facts. That this is not overemphasized may be illustrated by mentioning the many terms used to describe anxiety: the ego and the superego. In the title of this book, "stress" implies an almost physical quality which in the physical sciences can be measured weighed, and mathematically studied. By use of such terminology the authors seem to be striving to give their hypotheses factual qualities. Anxiety is described by such words as "free-flowing" "pressure" "blocking" "waving," and "free-floating." Such qualitative and quantitative expressions are in constant use, both in the clinical descriptions and in the pages which follow each case to interpret and explain the theories.

It should be noted again that the criticism of this book is not intended, primarily for the psychiatrically trained reader. It is written for those who are interested in finding out something about the war neuroses as a part of a general understanding of the neurotic personality which comes into the general experience of physicians whose interests lie chiefly in the field covered by *Surgery Gynecology and Obstetrics*. It should be made clear to the general reader that the conceptions of the neurotic mechanism, so insistently emphasized are not to be taken as verifiable, but rather as a working scheme for which the authors have a strong predilection. The reviewer is referring specifically to the dynamic

picture of the ego and superego mention of which is found on almost every page of this book. A critical examination of these Freudian concepts of the personality and of the theories of the neuroses built upon these concepts has no place in this review. As working hypotheses they have become the permanent possessions of present day psychiatry and their value cannot be overestimated. In this book, however the two systems and structures of the ego and superego act as beings and not as functions. They are endowed with capacities, qualities, and drives which are often specific and exclusive and leave with the reader the picture of a personality made up of two hostile gangs forever at odds with one another forever quarrelling for mastery with sly and cunningly devised plots and schemes providing an atmosphere reminiscent of the Kentucky or Tennessee mountain fends. In this embattled area, the writers find no place for the great instinctive contender—the id. Its omission is strange and it is not explained.

In the chapter on psychodynamics, the central item in the causation or in the strategy of the neuroses is anxiety. About the meaning and implication of this affective state there have been endless discussions and polemics. The key to the understanding of the neuroses is the understanding of anxiety. This understanding is not facilitated by limiting one's conception of anxiety to apprehension and to loss of some loved one or object nor by attaching its conscious reactions to the ego. Anxiety has to do with the totality of a human being. Such a fundamental thing, so tied up with the maintenance of the integrity of a being, cannot and should not be limited to only one part of the personality. Nor is it likely that anxiety has its roots in past experience nor does it necessarily depend on them. Anxiety seems rather, to be the affective response of a person to situations in which disintegration threatens. The integrity of the organism is at stake. Anxiety stimulates fear or even arouses it and thus the attachment to some specific object or objectives is facilitated. The term "free-flowing anxiety" and attached anxiety would seem to be a contradiction. It is a device used frequently by the authors to add a realistic touch to this and other emotional reactions by endowing them with physical qualities, such as flowing, damming up pressure, and so forth. There is little doubt of the usefulness of such devices, but one can wonder if the gain achieved in clarity is sufficient to neutralize the risk of fixing, in the reader's mind theoretic ideas of the distorted personality as established facts.

The readers of this book, and there should be a great many of them, will not all have knowledge of the methods of psychiatric interpretation. Lacking it, they may get impressions perhaps lasting ones, of a mechanical human being with devices for its actions in war and peace, for which no experimental proof has been obtained. It is for this reason that the reviewer has thought it necessary to point out some of the imperfections of the authors' thinking.

on these vital questions. The reader will be so interested and entertained by the case reporting and by the general story that he will fail to see anything out of the way with the planned dynamics of the men under stress. There is too much good in this book to warrant quibbling over what, to him, are unimportant matters.

Psychiatry has suffered in comparison with other branches of medicine from a tendency to a too ready acceptance of working hypotheses as facts. What appears to be aspects of the truth in personality structure are, in reality, simply outlines or frameworks to strengthen the explanation and interpretations. This leads a degree of smoothness and tangibility which is deceptive. For example, the clear picture from this book, of the ego and the superego in a chronic state of a fitful and a feuding, is a doubtfully accurate statement of what happens to a personality whose structure has been discordantly shocked by war experiences.

The average reader, and possibly the more technically trained one, will find the chief interest of this book to be in the treatment and handling of the war neurotic aviators rather than in the psychological interpretations of the thing that caused his military disability. He will lose interest in the question of anxiety, regression, the ego and the superego fights but will be concerned with what is being done for them therapeutically. The chapter on treatment and results is much more brief than its importance would seem to indicate. Thus at first sight, seems an error in value judgment. But this is only a superficial view because in the body of the book which is made up of protocols of individual cases the authors never lose sight of the treatment and the reasons for the many types of therapeutic efforts. One of the outstanding excellencies is the infiltration of the case reports with the treatment problems. Along with this there is discussion of the problems based upon the psychological schemata chosen by the authors. This includes the type of therapy used and the reasons for it in with the basic psychological schemes of the psychodynamics of the situation. As a result of this conception of clinical reporting the reader in each case report has the conviction that a therapy is in the process of being developed. There results a kind of completeness and wholeness as if the story were told from beginning to end.

The special chapter on treatment is therefore a summing up and the reader is prepared to accept what is written there because he has become pretty well acquainted with it before. This book deals almost exclusively with the aviation wing of the combatant forces and mostly in actual combat environment. Some material is from the convalescent hospital in this country where the authors are at present, in active service. The clinical material, therefore, includes the pilot, the crew, the ground forces and the rest of the personnel who comprise the working organization of a flying unit. This focuses the attention of the study on the activities of the members of the crew in combat photography

reconnaissance, flight formation, and so forth. The aviation wing of the forces is a very selective group from the standpoint of physical fitness, youthfulness, intelligence and technical training. The screening for aviation is much more meticulous than for the army as a whole. The possibility of physical defects, especially in the special sense organs is reduced to a minimum. The absence of certain phases of the neuroses among flyers as contrasted to the infantry can therefore be well understood. Flyers as a rule are better housed, fed, rested, and have better recreational facilities. All this adds up to the fact that they should be more amenable to effective treatment, though they more readily succumb to war traumas.

The mobility of the flying forces so important a factor in decreasing the number and seriousness of war neuroses in the ground forces is a constant and not an occasional factor. The stresses are, perhaps more violent, but their duration is more brief. Group organization is tighter, smaller and much more essential to the smooth working of a crew than it is in other arms of the services. All this means that on this material therapeutic efforts should be more effective than anywhere else in the services, even though there are necessarily few statistical confirmations.

No new types of treatment are described but there are novel and interesting modifications of methods used in the first World War. Narcosynthesis is far better organized and developed than was formerly possible. Hypnosis was used then and is in use now but is less effective, on the whole than pentothal sleep. Shock treatment, the most recent addition to the therapeutic measures in psychiatry has a very limited use in the flying forces. The authors are very right in discarding this method and their reasons for so doing are pertinent. They place their main emphasis on narcosynthesis and the somnolent state produced by intravenous pentothal. This represents an advance in procedure of great importance for this drug acts quickly and routinely with few bad aftereffects. Such a drug was not available in World War I and attempts at producing the same effect had to be made with cruder drugs such as earlier forms of the barbiturates, bromides and chloral hydrate. Ether and gas were also used for producing this somnolent state.

The use of dream material to obtain descriptions of experiences in an emotional state was regarded then, as now, as a valuable source of information about the individual soldier undergoing treatment. Group therapy not then called by such a good term was an automatic necessity owing to the large number of cases and the scarcity of trained psychotherapists. There is very little mention of these earlier efforts and no mention at all of the man who, without doubt, is responsible for the beginnings of the important place psychiatry has achieved in this war—Dr. Thomas Salmon.

It should be clear in the readers' minds how narcosynthesis works and what it attempts to accomplish.

It is well to repeat here that the authors regard the use of pentothal, not as a treatment, but as a means of acquiring repressed or forgotten material, which can then be joined to the ego function in an effective synthesis. Consciousness then becomes the final arbiter and can choose the proper and healthy utilization of the traumatic experiences as experiences. By so enabling the soldier to face himself, the original traumatic situation and its emotional consequences, psychotherapy plus narcosynthesis releases the energy by which he becomes an integrated personality. This is a sound and intelligent therapy and it does not matter much what descriptive terms are given to the mechanisms which are active in the process of synthetic build-up. This rough and skimpy sketch of the therapeutic purposes of narcosynthesis does not begin to consider the techniques that are necessary to accomplish this purpose. Careful psychiatric knowledge and experience are necessary. In this book, they are described with care and minuteness.

The authors give detailed consideration to the limitations of the military psychiatrist and point out, wisely, that his job is primarily a military one and defined by military needs. His main duty and responsibility is to return to active duty as many patients as he can, and to prevent the occurrence of a neurosis in as many combatants as is possible. If the military authorities are convinced of his good faith in these two essentials, his advice on the final disposition of cases is generally followed. In this respect, military psychiatry differs from its peacetime brother in the final therapeutic goal. To

change, revise and alter a disruptive environment is an important part of civil psychiatric effort. In war the psychiatrist cannot possibly affect the arrangement or qualities of combat or precombat areas. He should try to return his cured or neurotic to the traumatic environment that originally produced the neurosis. This war necessity cannot be too greatly stressed and in this book it is amply and emphatically pointed out.

Men Under Stress is a book which will take its place as a permanent contribution to the knowledge already accumulated of the neuroses in this and the first World War. In spite of its length and its hurried, breathless style in places, there is no question of its value and pertinence especially at the present time. Its appeal rests largely on the very human quality which the authors have put into their writing. It is the story of men under battle and war-borne stress. It is also the story of a small group of men, themselves in the atmosphere of conflict who give freely and generously of their training, experience, knowledge, and good faith, to help the infinitely larger group of men who have succumbed, temporarily or permanently to the forces in the stress and stresses of war. It is finally the story of conflict where the enemy is no longer the armed might of opposing armies but the unarmed might of the neuroses.

Eight years ago Freud wrote these words: "What is the source of the neuroses? What is the ultimate, its specific, underlying principle? After decades of analytic effort, this problem faces up as untouched as at the beginning." S. J. SCHWAB.

CORRESPONDENCE

SEGMENTAL RESECTION OF LESIONS OCCURRING IN THE LEFT HALF OF THE COLON WITH PRIMARY END-TO-END ASEPTIC ANASTOMOSIS—A Correction

IN the December 1945 issue of *SURGERY GYNECOLOGY AND OBSTETRICS*, volume 81, page 593 in the article entitled "Segmental Resection of Lesions Occurring in the Left Half of the

Colon with Primary End-to-End Aseptic Anastomosis: Report Based on Fifty Cases" by John M. Waugh and Monford D. Custer Jr., the authors erroneously stated that Gibbon and Hodge had reported the mortality after exteriorization operations on the colon as 99 per cent. The figure should have been 39 per cent (14 patients, 4 deaths) as stated in Table II in the article by Drs. Gibbon and Hodge.

INTERNATIONAL ABSTRACT OF SURGERY

VOLUME 82

FEBRUARY, 1946

NUMBER 2

ABSTRACTS OF CURRENT LITERATURE SURGERY OF THE HEAD AND NECK

HEAD

Campbell E. H., Jr. Compound Comminuted Skull Fractures Produced by Missiles. *Ann Surg* 1943 122 35

One hundred cases of compound, comminuted fractures of the skull produced by missiles are analyzed. More wounds were caused by shell fragments than by all other means. Inner table fractures were sometimes overlooked and occasionally led to serious complications. Tripod incisions often gave trouble. It is recommended that they be avoided when possible. Convulsions were uncommon in the first few weeks; their occurrence was sometimes an early manifestation of abscess formation. Subdural hematomas were present in but 2 cases. Nineteen patients developed superficial wound infections of varying degrees, while 23 developed deep-seated infections. These were manifested by abscess, meningitis, cerebral fungus, or some combinations thereof. There were 5 deaths, all of which occurred in the latter group.

Incomplete débridement was the largest single factor contributing to wound infection. In those cases in which all bone fragments had been removed, infection was uncommon and seldom deep, whereas if débridement had been incomplete or had not been performed at all, infection was common and usually deep. Bacteria cultured from these wounds were principally skin inhabitants of low virulence.

Treatment consisted in the evacuation of pus and removal of associated bone fragments and/or metallic foreign bodies, as well as of adjacent necrotic tissue and old blood. Abscess capsules were disturbed as little as possible. Sulfonamide therapy was employed as an adjuvant. Failures resulted only in those 5 cases in which for one reason or another this procedure was not carried out.

Experience, judgment, and skill, as well as proper neurosurgical armamentarium are prerequisites to good primary débridement. It is recommended therefore that patients with severe head wounds be evacuated as directly as possible to a hospital in which these are available, even though a few additional hours be required.

Following the submission of this article in April, 1944, the number of penetrating wounds of the skull treated in the Mediterranean theater of operations increased several fold. Figures based upon 974 cases from the Tunisian, Sicilian, and Italian campaigns show the incidence of deep infection to have been 12.2 per cent. During the past year in particular débridement has been carried out with more thoroughness. Penicillin therapy (25,000 units given intramuscularly every three hours) has been the routine procedure. As a result, the rate of deep infection has been further reduced.

EYE

Bland, J. O. W. and Wilson, R. P.: Bacteriological and Clinical Observations on the Treatment of the Acute Ophthalmias of Egypt with Sulfonamides and Penicillin. *Brit. J. Ophth.*, 1945 24 339.

The authors describe their bacteriological and clinical observations on the treatment of the acute ophthalmias of Egypt with sulfonamides and penicillin. They point out that the acute ophthalmias of Egypt are caused by bacteria which are sulfonamide sensitive and that treatment with sulfonamides is simple, safe, and effective. Sulfonamides provide the solution (for Egypt and other oriental countries) not only for the treatment of affected patients but also for checking and eradicating yearly epidemics, because they reduce the period of discharge from 6 to 1 or 2 days and render cases noninfective 12 hours after administration of the drug.

For every 10 kgm. of bodyweight, 0.5 gm. of sulfonamide was given in 24 hours as two doses, a single dose corresponding to the usual 6-hour dose which yields a concentration of from 5 to 10 mgm. per 100 c.c. of blood. Because the dosage based on bodyweight is not always convenient or practical, and because most cases occur in children under 10 years of age, a dosage based on age is suggested: twice daily 3/4 tablet (3/8 gm. tablet) at from 0 to 3 months; 3/4 tablet at from 3 to 6 months; 1/2 tablet at from 6 to 12 months; 3/4 tablet at 1 year; 3/4 tablet

at 3 years 1 tablet at 6 years 2 tablets at 9 years and 3 1/2 tablets at 20 years.

The authors conclude as follows regarding the acute epidemic ophthalmia (Koch-Weeks and gonococcal) of Egypt

1 A single dose of sulfonamide reduces the bacteria in 4 hours and suppresses them in about 12 hours which cures a considerable proportion of gonococcal cases by a single dose except the more resistant Koch Weeks cases

2 Two doses of sulfathiazole or sulfadiazine in one day at an 8-hour interval will cure practically all cases except Koch Weeks cases

3 Two doses on successive days will cure all cases of gonococcal and Koch Weeks ophthalmia

4 A single intramuscular injection of penicillin reduces gonococci to nil in 3 or 4 hours however repeated doses are necessary at short intervals to ensure a cure because relapses may occur in from 10 to 12 hours after a single dose

5 As penicillin has no effect on Koch-Weeks cases it is unsuitable for treatment of acute Egyptian ophthalmia

JOSHUA ZUCKERMAN, M.D.

EAR

Machle, W: Effects of Gun Blasts on Hearing. *Arch Otolaryngol* 1945 4: 164.

The characteristics of the hearing loss following controlled exposure to gun blast are like those of deafness from sustained high noise levels. Acoustic injury and loss are common in gunnery instructors, artillerymen and others potentially serious partial deafness may be expected to occur in significant numbers of military personnel. With repeated equal exposures acoustic damage is cumulative apparently largely because recovery from the initial traumatic response is incomplete in the 24 hour intervals.

Partial recovery of hearing regularly occurs in the first few days after cessation of repeated daily exposures up to six or eight. The rate and the extent of the ultimate recovery from the losses following long periods of exposure need to be further defined. After months of exposure, recovery to pre-exposure levels of acuity is doubtful there was evidence of partial recovery in only 1 of 10 men studied.

Preliminary observations indicate that the obvious relationship between magnitude of exposure, measured by blast pressures and the resultant hearing loss cannot be narrowly defined because of great variability in the response of individual subjects as well as uncontrollable variables in the behavior of blast waves

NOAH D. FABRICANT, M.D.

Periman H. B.: Reaction of the Human Conduction Mechanism to Blast. *Laryngoscope*, 1945 55: 477

An experimental investigation of the effect of explosions on the human conducting mechanism was carried out on fresh temporal bones.

The stimulus used was the shock pulse from a .33-caliber blank cartridge fired from a starting pistol

held near the external auditory canal of the fresh preparation.

Protection to the ear is considered and illustrative records are presented.

JOHN F. DUNN, M.D.

Shilling, C. W.: Aero-Otitis Media and Loss of Auditory Acuity in Submarine Escape Training. *Arch Otolaryngol* 1945 41: 69.

Since 30 per cent of the men undergoing submarine escape training at the United States Submarine Base at New London, Connecticut have had aural difficulty leading to aero-otitis media and resultant loss of auditory acuity the author presents an analysis of the extent of the damage associated with this training and outlines possible preventive and therapeutic procedures.

He believes certain preliminary observations can be made and some opinions hazarded at this time

1 All ears showing severe damage, grades 3 and 4 have thus far been found to have flattening of the eustachian orifices due to lymphoid hyperplasia, and thus roentgen rays and radium should be of great benefit.

2 Aero-otitis media has been noted to be associated with a depressed prepressure audiometric curve

3 Under conditions of careful selection of the patients and proper administration of pressure, severe otopathological observations with associated losses of acuity need not be as common as they have been

4 Since this type of trauma leads to acute auditory damage repeated trauma may result in permanent auditory damage.

NOAH D. FABRICANT, M.D.

Barton, R. T.: The Influence of Pregnancy on Otolosclerosis. *N England J Med* 1945, 233: 431

The records of 133 otosclerotic women who had experienced one or more pregnancies were reviewed. Sixty four per cent were stated to have been made worse by at least one of their pregnancies. Over half of these experienced the onset of hearing loss immediately after parturition (during the lactation period), and 19 per cent 6 months or more after ward. Seventy per cent noted the hearing loss in the first pregnancy, 16 per cent in the second and the others from the second to the seventh pregnancies.

In 30 per cent of the cases the hearing loss was noted only during one pregnancy and unaffected by others.

The conclusion is made from the review that many otosclerotic patients are adversely affected by pregnancy but there is little uniformity in the time of onset of the impairment and no regularity in the effect of successive pregnancies.

No records of the hearing before and after pregnancy are presented in this article.

The literature is reviewed on the question of interruption of pregnancy. The author concludes that abortion is never justified because (1) the effect of pregnancy on otosclerosis is unpredictable (2) abor-

tion may not arrest the progression of the deafness, and (3) the disease does not endanger the life of the mother

JOHN R. LINDSAY M.D.

Allman C. H. Penicillin in Otolaryngology *J Am Med Ass* 1945 129 109

In a series of 5,640 cases of scarlet fever, 9 per cent of the patients developed otitis media. Typings of the organisms cultured from the throats were done on 300 of these patients and all showed *Streptococcus hemolyticus* type 17. These organisms were resistant to sulfadiazine in *in vitro* studies. Over 75 per cent of the patients with scarlet fever had received sulfadiazine prophylactically from a few days to two months prior to the development of the disease. About 10 per cent of the patients had received penicillin from the time of onset of the disease and in these the incidence of otitis media was reduced approximately one half.

All patients with otitis media received 10,000 Oxford units of penicillin by intramuscular injection every three hours from the onset of the condition until two days after all signs had subsided. Local treatment to the ear was limited to dry wiping or in some cases, hot saline irrigations. There were 33 cases (0.56%) requiring mastoidectomy. In these, the operative wound also was irrigated with penicillin solution through a soft rubber tube secured in the cavity which otherwise was closed. From 5 to 10 c.c. of a solution containing 500 units per cubic centimeter was instilled every four hours.

All of the patients recovered and there was not a single case of a chronic discharging ear. With the exception of 3 cases in which the lateral sinus was opened, recovery was complete within a period of seven days.

There were 2 cases of meningitis in patients who had not received penicillin. Mastoidectomies were done on both patients. They were given 100,000 units of penicillin intravenously the first twelve hours, 15,000 units intrathecally immediately, 10,000 units intramuscularly every 2 hours for 2 days and every 3 hours thereafter until recovery was complete. Four grams of sodium sulfadiazine every 6 hours for a period of 2 days was also given intravenously. Recovery was rapid.

Penicillin was used in the same way in 14 cases of nonscarlet fever mastoiditis, with equally good results.

The use of penicillin is given credit for the reduction of morbidity to a minimum in this large group of cases of otitis media and there were no deaths.

JOHN R. LINDSAY M.D.

Macbeth R. G.: A Series of 50 Cases of Acute and Subacute Mastoiditis Treated by Closure of the Wound and Perfusion with Penicillin *J Laryngol Otol* 1945 60 16.

A series of 50 cases of acute or subacute mastoiditis in which penicillin was used postoperatively by perfusion are presented by the author. Unusual care was taken to get as complete hemostasis as pos-

sible following which a fine rubber tube was inserted at the upper end of the wound and sewn into place. The wound was closed completely. Penicillin solution was then run into the wound until it oozed out of the incision line. The concentration varied from 250 to 500 units per cubic centimeter.

Dressings were not disturbed for 5 days. During this time at 6-hour intervals the wound was evacuated and then filled with the penicillin solution.

Of the 50 cases treated, 9 were failures from the standpoint of early healing but all eventually healed.

The predominant organism was the *Streptococcus hemolyticus*.

No severe complications resulted and the technique was carried out easily by the nursing staff.

JOHN F. DREW, M.D.

MOUTH

Thomas K. H.: Functional Disturbances following Fracture of the Mandibular Condyle and Their Treatment *Am J Orthodont* 1945 31 575

The causes, diagnosis, treatment and prevention of complications following the treatment of condylar fractures are described by the author. Five cases presenting major functional disturbances are reported. In order to obtain a clear picture of the condition present, recommendations are advanced regarding the use of various positions in x-ray examination.

The prevention of complications includes exact reduction by the open method and internal wiring, plating or skeletal fixation. In fractures with displacement, interosseous wiring gives excellent results. In fracture dislocation, skeletal fixation of the condyle to the temporal bone is recommended in addition to the wiring. The two methods may be replaced by the use of the Sherman plate. Two cases of fracture dislocation illustrating the two methods are presented.

NOAH D. FARRINGTON M.D.

NECK

Harrington S. W.: Pulsion Diverticulum of the Hypopharynx at the Pharyngoesophageal Junction *Surgery* 1945 18 66

In a series of 140 cases of pharyngoesophageal pulsion diverticulum, 107 of the patients were men and 33 were women. Their ages varied from 34 to 80 years, the average age being 57 years. In 80 per cent of the cases the symptoms were vague at onset and slowly progressive. In 20 per cent they were more rapid in progress. The duration of symptoms was from 1 to 25 years, the average duration before operation being about 5 years. Fifteen patients had marked obstruction of the esophagus and 3 had complete obstruction at the time of admission.

The earliest symptom usually is dysphagia. Later food and mucus are regurgitated. After the sac has become well developed its enlargement is more rapid than before because of the increased pressure from within caused by retention of food and secretions.

tions Progressive esophageal obstruction often occurs and the patient's loss of weight may be great.

When a large sac that extends into the mediastinum is filled with food it produces marked pressure on the adjacent intrathoracic organs and causes a distressing sensation of fullness in the thorax, which often is associated with dyspnea palpitation of the heart and a sense of suffocation. Severe cough and choking spells frequently occur. Many times patients lower their heads, as is customary in postural drainage, and then press on the side of the neck in order to empty the sac. In some instances food may enter the trachea and cause marked cyanosis.

Repeated aspiration of food into the bronchi may result in bronchitis or bronchiectasis. In this series of 140 cases, bronchitis was present in 9 cases, and bronchiectasis in 4. Associated hoarseness of the voice also occurs. This is caused by pressure or inflammation around the recurrent laryngeal nerve, which is often close to the neck of the sac. In this series of cases, hoarseness was present in 8 cases; the vocal cord was fixed in 3 cases.

After the sac has become definitely formed, the symptoms are definite and characteristic. The diagnosis usually can be made on the basis of the symptoms, but it should be proved by roentgenographic examination. In the earlier stages when the symptoms are vague, a definite clinical diagnosis may not be possible without an esophagoscopic or roentgenological examination. These methods are the most accurate in the establishment of a definite diagnosis and the author believes they should be employed in all cases in which there are persistent signs of dysphagia. The longer the diagnosis is delayed the greater is the risk of serious complications which may enhance the difficulties and may impair the results of surgical treatment.

Complete removal of the sac, including its neck, is generally accepted as the only effectual surgical procedure for pharyngoesophageal diverticulum. The technical difference in the two operative procedures advocated to accomplish this purpose is in treatment of the sac and the time of its removal. In the one-stage procedure the sac is removed at the primary operation. In the two-stage procedure a temporary diverticulectomy is performed and the sac is removed at a second operation seven to ten days later. The fundamental difference in these two procedures is that in the one-stage operation the fascial planes leading to the mediastinum are not walled off prior to removal of the diverticulum and in the two-stage operation the interval between the operations permits the formation of granulations which wall off the fascial planes of the neck and mediastinum. In this series of 140 cases, the one-stage operative procedure was performed in 113 cases and the two-stage procedure in 25 cases.

Patients who have lost considerable weight as a result of their inability to obtain sufficient nourishment require preoperative feeding. In most instances this can be accomplished by an indwelling stomach tube. Sixteen patients in this series of 140 cases

were prepared for operation by this means. In one case in which complete obstruction was present it was impossible to pass the stomach tube, and a preliminary gastrostomy was necessary for feeding.

Dilatation of the intralutal of the esophagus is advisable and has been performed routinely in the last 50 cases of this series. In many instances the intralutal is distorted and dilatation minimizes the danger of exerting pressure at the site of closure of the pharynx when the patient swallows food postoperatively.

In all cases in which there is any evidence of retention in the diverticulum, a roentgenological study of the thorax should be performed immediately before operation. The reason for this is it is certain that no barium has been retained in the diverticulum, which at operation might be aspirated into the lungs. In those cases in which retention exists, the diverticulum should be irrigated thoroughly to remove the contents.

The vocal cords should be checked both preoperatively and postoperatively. In any case in which the patient has symptoms of hoarseness it is advisable to check the vocal cords preoperatively.

A thread which is passed through the esophagus into the stomach the night before operation is left in place until the patient is taking nourishment satisfactorily after operation. This provides a guide over which a stomach tube can be passed if a postoperative pharyngeal fistula should develop. This, however, may be unnecessary since only one of the author's patients has required passage of a stomach tube postoperatively because of a pharyngeal fistula. Formerly the author left a stomach tube through the esophagus at the time of operation, but this practice was discontinued because the tube was often irritating to the esophagus and produced considerable mucus which may be detrimental to healing of the pharynx.

Operation should not be undertaken if the patient has had a recent infection of the throat or lungs, because of the danger associated not only with infection of the throat but also with cough postoperatively, both of which would interfere with the healing of the tissues.

The author prefers regional nerve block by the use of procaine. This method permits the patient's reflexes to remain active, which is a helpful safeguard in many instances. If an accumulation of secretions is present in the sac at operation, these secretions can be carefully emptied into the pharynx; they may be either aspirated by suction or swallowed. The act of swallowing is often helpful in identifying small diverticula, as air is forced into the sac. The surgeon also finds it helpful if the patient can talk during dissection around the neck of the sac posteriorly because of the close proximity of the recurrent laryngeal nerve. This is true particularly in those cases in which, because of considerable inflammatory reaction around the neck of the sac and in the surrounding tissues, visualization of the nerve is difficult.

Fig 1. One-stage diverticulectomy. a, Incision along anterior border of sternocleidomastoid muscle, retracting the thyroid medially and the carotid sheath with the sternocleidomastoid muscle laterally. The peritracheal fascia is incised at the level of the cricoid cartilage, to expose the diverticulum. b, Dissecting the diverticulum from the peritracheal fascia and elevating it from the fascial planes, starting at the neck of the sac. c, Dissecting the true neck of the sac from the surrounding muscles of the posterior wall of the pharynx. d, Transfixing and ligating the neck of the sac with chromic catgut. e, Invagination of stump of sac into wall of pharynx. f, Closing the opening in the muscles of the posterior wall of the pharynx with chromic catgut.

The method of approach to the diverticulum depends on its location but it should be from the side of the neck on which the diverticulum is situated. If the diverticulum originates in the midline, the author prefers a left cervical incision. Diverticula usually occur on the left side but in many instances occur on the right side. In this series of 140 cases the approach was through the left cervical region in 126 cases and through the right cervical region in 24 cases. In one case an infected diverticulum was removed through the left cervical approach. The diverticulum subsequently recurred on the right side and the approach was through a right cervical incision.

The side of the neck from which to approach a diverticulum is determined by a careful study of the anteroposterior roentgenogram. In some instances in which determination of the exact position of the neck of the sac is difficult, esophagoscopy examination is of value.

In the one-stage procedure the incision is made through the skin and platysma myoides muscle and along the anterior border of the sternocleidomastoid muscle from the hyoid bone above to a point about 3 cm above the clavicle. The external jugular vein

is often in the line of incision. In these instances the vein is cut and ligated. The sternocleidomastoid muscle then is separated from the omohyoid and sternothyroid muscles. The latter are retracted medially. This exposes the carotid sheath which with the sternomastoid muscle, is retracted outward. The thyroid gland is exposed and retracted upward and medially. This exposes the peritracheal fascia which surrounds the trachea and esophagus. If appreciable hypertrophy of the thyroid gland is present, partial lobectomy may be necessary in order to obtain adequate exposure of the fascial coverings of the diverticulum. In many instances particularly if the diverticulum is approached from the right side the inferior thyroid artery and vein course over the diverticulum and in these cases the vessels should be cut and ligated. The fascia then is incised posterior to the trachea at about the level of the cricoid cartilage. The neck of the diverticulum usually is located readily at a point opposite the level of the cricoid cartilage.

Several methods such as the use of bougies and the esophagoscope, have been suggested for locating the diverticulum but the author has not found these methods necessary. There is never any difficulty in

locating the larger types of diverticula as they lie lateral or posterior to the esophagus. The small diverticula, which often are buried in the cervical fascia, can be located readily by the simple procedure of having the patient swallow or air may be forced into the diverticulum. The location of diverticula that occur through the posterolateral wall of the pharynx is greatly facilitated by approaching them from the side of the neck from which they originate. If a diverticulum originates from the right posterolateral wall of the pharynx and is approached from the left side, there may be considerable difficulty in locating it as well as in visualizing the neck of the sac.

After the diverticulum has been located the fascial coverings are carefully dissected away until the true wall of the sac is reached. The fundus of the sac is elevated into the wound and dissection of the neck of the sac is carried out as it appears through the muscular wall of the pharynx. Great care should be exercised to this dissection to avoid perforation of the sac or injury of the surrounding structures, particularly the recurrent laryngeal nerve. This nerve is often in close proximity to the neck of the sac, particularly in those cases in which the sacculation passes through or beneath the cricopharyngeus muscles. It is important not to separate the fascial planes more than necessary to remove the body of the sac, particularly when the diverticulum extends into the mediastinum.

After the sac has been completely dissected free from the surrounding structures the true neck of the sac is dissected from the pharyngeal muscles. Particular care is taken to separate and remove any fibers of the inferior constrictor muscle and of the cricopharyngeus muscle above and beneath the neck of the sac, respectively. In many of the larger diverticula, the opening into the pharynx is large and consists essentially of diffuse bulging of the back wall of the pharynx. In this type, great care should be exerted to determine the true relationship of the opening of the sac to the muscular wall of the pharynx which often is much thinned out. It is important to dissect these diffuse sacculations from the muscle and to establish as small a neck to the sac as possible, with care not to remove too much of the mucous membrane because of the danger of producing a stricture. After the true neck of the sacculation has been isolated from the surrounding muscles, it is transfixed by the use of chromic catgut and the diverticulum is completely excised. The stump of the sac is then invaginated into the wall of the pharynx and the muscles of the wall which surrounded the neck of the sac are closed with interrupted catgut sutures. The silk thread which is through the esophagus is pulled taut by the anesthetic before the neck of the sac is ligated so that there is no danger of including it in the closure of the neck of the sac. A soft rubber tissue drain is placed in the pocket formerly occupied by the diverticulum but it is not placed at the site of closure of the pharyngeal wall. The wound is closed by the use of interrupted sutures.

In the 115 cases in which the one-stage operation was performed, there were no operative deaths. A temporary pharyngeal fistula developed in 5 cases. In 3 cases hoarseness occurred in 2 to 3 days after operation and subsided within 1 week or 10 days. In one case in which the patient had hoarseness of the voice before operation paralysis of the cord occurred and the hoarseness continued. The average duration of convalescence in the hospital was less than 2 weeks and the average period of time to dismissal was 3 weeks.

In 5 cases angulation of the esophagus required dilatation. The diverticula recurred in 2 cases in one of these the symptoms improved after dilatation but operation subsequently may be required. In the other case, a second operation was necessary.

The author believes there is little risk of mediastinitis after a one-stage operative procedure because in none of his cases has a fistula developed before 72 hours after operation. By that time the mediastinal fascial planes are well off. However it is important not to separate any more of the tissues of the mediastinal fascial planes than is essential, and to remove the diverticulum starting at the neck of the sac.

Fifteen of the 115 patients in this series had large diverticula that filled the entire mediastinum. In several instances they extended into the thoracic cavity. The largest one held 825 c.c. of fluid. There was no suggestion of mediastinal infection after operation in any of these cases.

The results of operation in the 25 cases in which a two-stage operation was performed were as follows. There was 1 operative death in the case of a patient who had Parkinson's disease. Although this death was attributed to the operation, it was the result of his poor general condition; the latter was caused by weight loss as a result of his inability to take nourishment because of the diverticulum as well as advanced Parkinson's disease. A temporary fistula developed in 6 cases. In 3 cases there was temporary hoarseness and in 1 case there was paralysis of one vocal cord. The average convalescence before dismissal from the hospital was more than 5 weeks.

Five patients had angulations that required subsequent dilatations. There were 3 recurrences, all of which were treated by dilatation. Two patients subsequently may require surgery.

Neel, H. B., and Pemberton, J. D.: Lateral Cervical (Branchial) Cysts and Fistulae. *Surgery* 945
8 857

Congenital cysts and fistulas which appear on the lateral aspects of the neck are referred to as branchial, ventral, and lateral cervical. There is no unanimity of opinion as to the etiology of these lesions. The work and theory of Wengowski, however, have greatly influenced thought on this subject.

Several members of the same family and of one or more generations may be afflicted. Other congenital lesions also are encountered occasionally in patients with lateral cervical cysts and fistulas.

Involved the accessory sinuses the roentgenographic examination frequently showed much more extensive involvement than was suspected from the clinical findings. In several instances a tumor that appeared clinically to involve only the maxillary sinus and nasal fossa was found by roentgenographic examination to be present in the ethmoid cells and frontal sinus as well. In this group, too malignant destruction of the floor and walls of the maxillary sinus, ethmoid cells, orbit, nose, and zygoma was evident at times. In one case in which a nonulcerated tumor protruded from the vault of the nasopharynx, roentgenograms showed extensive destruction of the sella turcica and cloudiness of the sphenoid sinus which revealed that either of these regions was the site of origin of the neoplasm. Roentgenograms of the thorax were normal in all of the patients at the original examination at the clinic.

Only in one of the 11 cases was metastatic involvement of bone demonstrable roentgenographically at the time of the primary examination at the clinic.

This was a case of a huge, rapidly recurring tumor of the upper jaw, maxillary sinus, ethmoid cells, and nasal fossa. Roentgenographic examination of the maxillary sinus disclosed not only extensive destruction of the upper jaw, maxillary sinus, and ethmoid cells but what appeared to be multiple areas of metastatic destruction throughout the skull as well. The patient had no symptoms referable to the secondary tumors. The metastatic involvement might well have furnished a clue to the nature of the lesion had the patient been observed prior to partial removal of the neoplasm of the superior maxilla and cheek. The trauma attendant on this therapy had produced extensive sloughing and inflammatory reaction so that the condition strongly suggested a fulminating type of squamous-cell carcinoma. Although the tumor of the upper jaw and maxillary sinus had been noticed by the patient for only three months it was assumed that the malignant process was primary in this situation and that the smaller deposits observed throughout the calvarium were secondary.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

White, J. C.: Pain following Injuries of the Peripheral Nerves. *U S Nav Med Bull.*, 1945 45 845

The problems outlined in this article have occurred innumerable times during the present conflict, and neurosurgeons and neurologists have had ample opportunity to study and evaluate them. Yet there is still no complete unity of opinion with regard to the underlying mechanisms. Painful stimuli may be due to faulty regeneration, sepsis and scar tissue formation, although anoxia plays an important role. Anoxia may be due to local scarring or widespread vasoconstriction. Vasoconstriction is particularly liable to play a part in emotionally unstable persons with vasospasm. Direct cross stimulation of sensory nerve fibers by afferent sympathetic impulses is a theory which deserves careful consideration. There are two types of intractable pain commonly associated with peripheral nerve injuries: the phantom limb pain and the causalgic pain. The phantom limb pain often shows psychic manifestations in that it may come and go with the patient's frustrations and achievements.

The treatment of pain in peripheral nerve injuries is satisfactory and more or less straightforward, and it is clearly shown that certain outmoded methods are to be avoided. These methods include reamputation, chemical blocking of nerve trunks at gradually ascending levels, repeated resection of neuromas, periaxillary sympathectomy, subarachnoid injection of alcohol, and posterior root section. There are two procedures which have proved to be of value: the first for painful neuroma, and the second for causalgic states. A painful neuroma may be resected once if the pain is localized and if the pain is relieved by procaine block. At operation there are three ways of dealing with the neuroma: (1) the injection of 20 per cent formalin into the stump; (2) pulling the nerve through a drill hole in a neighboring bone; and (3) wrapping the nerve in a cuff of tantalum foil.

In the causalgic states the diagnostic test is paravertebral procaine block, and in the event that the pain is relieved during the period of the block, good results may be expected from appropriate sympathectomy. Sympathectomy however is more effective when pain is principally in the peripheral part of the limb.

There are cases of phantom limb in which the relatively harmless procedures described are not satisfactory and recourse must be had to operations on the central nervous system. There is no unanimity of opinions about the efficacy of these. Cordotomy and either postcentral cortical resection or lobotomy are possible methods of attack. With regard to cordotomy a diagnostic test can be done by using spinal anesthesia for the lower extremity and brachial plexus block for the upper extremity. A more

careful preliminary use of these diagnostic tests will increase the satisfactory results following cordotomy. In cases in which the pain is definitely of central origin resection of the postcentral cortex appropriate to the involved area of pain may give relief by removing the sensory cells which give rise to the phantom sensation. Lobotomy or interruption of the frontal association fibers may remove the patient's introspection and concentration on his defect.

ADRIAN VERBROEGHEN M.D.

BRAIN AND ITS COVERINGS CRANIAL NERVES

Clarkson P., and Schorstein, J.: The Treatment of Denuded Skull Table. *Brit. M J* 1945 2 422

The treatment of widely denuded areas of the calvarium has usually required a lengthy period of hospitalization and care because healthy granulation tissue must grow from the diploic spaces after numerous burr holes are placed through the external table.

The authors present a technique of early skin grafting which had been used in 3 cases with complete loss of scalp and pericranium over the area. Burr holes were placed only through the outer table arranged in a mosaic pattern, and connected with grooves produced with a gauge. The outer table was then chiseled away in small blocks to expose the entire diploic of the denuded area. Hemostasis was obtained with hot packs; however, bone wax was used in 1 case without detriment. Thin patch grafts 1 cm. square were then placed directly upon the diploic covered by a nonadherent material and maintained in place by tulle gras wool or crepe. The dressings were removed on the fourth day and then changed daily until healing ensued. Good results were obtained in all 3 cases. JACK I. WOOD M.D.

Wachowski, T. J., and Chenuault, H.: Degenerative Effects of Large Doses of Roentgen Rays on the Human Brain. *Radiology* 1945 45 33

The authors have reviewed the literature from the standpoint of the effects of roentgen rays on the human brain. There is a good deal of evidence to indicate that large doses of roentgen rays produced definite degenerative changes in the brain. These degenerative changes in some instances were reported in association with an increase of lipochrome substance within the cells. The nerve cells were affected most and the neuroglia to a lesser extent. The blood vessels for the most part seemed unaffected. Such changes were reported following the use of 12,645 r (air) through multiple portals over a period of 5 months.

More marked degenerative changes following even larger doses included alterations in the astrocytes, microglia, and possibly the oligodendroglia.

The authors have reported on 6 patients in 4 of whom the tumors were histologically verified prior to irradiation. Treatment consisted of the use of from 3 to 5 portals with an initial dose of 150 r increased over a few days to 300 r. The shorter series ran 32 days, totaling 9,000 r (air) and 6,150 r tumor dose; the longer series took 106 days with 14,540 r (air) and 8,800 r tumor dose.

Three of the cases came to autopsy and these showed extensive degenerative changes in the nerve tissue.

Pathological studies reported by the authors indicate that following irradiation of the brain there are widespread changes which affect all the cellular elements. The nerve cells of the cerebral cortex are almost universally degenerated, the least change being seen in the large Betz cells of the motor cortex. The neuroglial cells, especially the protoplasmic cells of the cortex, are fragmented and the fibrillary neuroglial cells are swollen. Fat has accumulated in their cytoplasm.

There is an increase in the number of microglia cells of huge size with their processes laden with fat or greenish pigment. The capillaries and other small blood vessels have excessive amounts of fat in the endothelial and adventitial cells. The myelin sheaths are swollen and fragmented giving rise to accumulations of fat in the white substance. The nerve fibers are also swollen and fragmented. In the adventitial spaces are accumulations of lymphocytes, plasma cells and macrophages. There is therefore a degenerative change affecting all parts of the brain and all its cellular elements even of the cerebellum.

HOWARD A. BROWN, M.D.

O'Connell, J. E. A.: *Lumbar Puncture in the Treatment of Penetrating Wounds of the Brain.* *Lancet* Lond. 1945 249 339.

The dangers of lumbar puncture in intracranial hypertension have been amply set forth but the value of this procedure for control has rarely been given a great deal of consideration. Although most neurosurgeons use spinal puncture in head injuries, the specific theory and indications have not been the subject of a special discussion. Penetrating wounds of the head provide material from which such a discussion may be launched. Of over 1,000 head injuries dealt with in the post hospital where the author was stationed, 150 were penetrating wounds. Various conditions arise in which lumbar puncture may be of service, namely, in post operative reduction of cerebral pressure in scalp wounds with penetration, in removal of intracerebral foreign bodies, in post traumatic cerebral abscess in untreated wounds seen after infection has set in, and in the treatment of progressive cerebral fungation.

There may be sufficient pressure from cerebral herniation on a scalp wound to cause anxiety about the strength of the suture line. When primary healing has taken place the danger of cerebral fungus is passed and that anxiety need no longer be entertained. During the period of healing lumbar puncture

will be found of value to reduce pressure on the wound. Cerebral herniation may have occurred before the patient is available for treatment and the brain wound may contain various bone and metallic fragments which are inaccessible partly because of the herniation. The track containing foreign bodies may be compressed in the herniated brain tissue. Lumbar puncture under these circumstances will reduce the herniation and open up the track of a driven fragment which makes their essential complete removal much easier. The puncture is done immediately before the débridement is begun. Even much the same situation exists when a post traumatic abscess has formed and the sinus track is compressed in a cerebral herniation. Lumbar puncture immediately before operation will open up the track and facilitate drainage and packing of the abscess cavity. The author packs such a cavity with rubber sheeting in which strip gauze is inserted forming a tampon which provides drainage outside of the rubber. The sheeting is changed frequently following lumbar puncture. Penicillin is used locally.

A patient with a penetrating wound may be considered too ill for surgery when first seen and, later after a few days survival, his untreated wound may be infected. Such a patient is almost certain to have a cerebral herniation through a dural defect. Lumbar puncture may be used to open up the track, which facilitates cleansing the wound and drawing it with a rubber sheeting tampon.

Progressive cerebral fungation is an obstinate and difficult complication of a large penetrating wound of the head. In this case the herniation may contain part of one of the lateral ventricles. The dilated distorted ventricle may in fact be the cause of the herniation. Lumbar puncture diligently used may cause the withdrawal of the herniation and ventricle into the cranial cavity.

In the cases under discussion, the lumbar puncture was done under anesthesia immediately before operation and the level to which the intracranial pressure was lowered depended on the circumstances of the case. After operation puncture was done once a day, the patient's head was kept high, and his fluid intake was regulated. Puncture was not done in cases in which the wound was thought to involve the lateral ventricle for fear of aspirating foreign material into it. Apart from the considerations mentioned lumbar puncture was of value in diagnosis and as a route for the introduction of penicillin. This excellent article is well illustrated and documented with case reports.

ADRIEN VERBURGH, M.D.

Martin, H. and Reese, A. B.: *Treatment of Bilateral Retinoblastoma (Retinal Glioma) Surgically and by Irradiation; Report on Progress.* *Arch. Ophth.* Chic., 1945 33 429.

The authors have made a special study of bilateral retinoblastoma and have offered a previous report one in 1936 with a discussion of 6 cases, and one in 1942 in which 4 new cases were added. This article

is a report of progress with regard both to the technique of treatment and examination and also the end-results of such treatment. Fourteen additional cases are discussed.

The five-year end results in 9 cases treated surgically and by irradiation are of interest in that 6 of 8 patients who were treated prior to 1939 are still living. In 1 case the cause of death may not have been connected with the original growth. Two of the 6 living patients can see and 4 cannot.

A comprehensive table showing the location, size of the tumor, treatment and end result in those 24 cases is appended. The first sign of the tumor is usually a white light reflex in the pupillary region of the eye; this may lead to examination and recognition of the disease which is usually bilateral. Tumors that occupy more than one quadrant of the fundus have a poor prognosis. Raised nodular tumors are unfavorable. Irradiation is relied upon to a great extent and the signs of improvement under this method are described; they consist chiefly of a gradual increase in the calcium content of the tumor to the point where it has the appearance of a single nodular mass of calcium resembling cottage cheese. The roentgen rays must be used with caution for the eye has a limited tolerance to them. The precise method to be used is described in detail; the single dose is about 400 roentgens and the maximum total dose 8 000 roentgens $\times 2$.

It is recommended that the child be frequently re-examined and this is best done under light chloroform anesthesia. ADRIEN VERBRUGHEM M.D.

SPINAL CORD AND ITS COVERINGS

Nielsen A., and Patterson G. H. Spinal Cord Tumors in Children; A Study of 3 Cases of Ependymoma. *J. Pediat. S. Louis*, 1945 27 515

Most medical men are of the opinion after reading authoritative works on spinal-cord tumors that these are rare in children. Among the older writers however there is evidence that these lesions occurred more frequently in children. In modern works the percentage varies from 1 to 5 per cent, but in older works it varies from 10 to 13 per cent.

The present article has to do with 3 cases of spinal cord ependymomas in children. In 1 of these the result was very satisfactory in that the patient is still alive after three and one-half years. The diagnostic problem is the important one for in all 3 of the cases reported the preliminary diagnosis was incorrect and treatment was instituted without improvement. Tuberculosis and poliomyelitis were the entities mistaken for the spinal-cord tumor in these 3 cases. The history however should have given a clue, for in all of the cases the trouble commenced with pain and stiffness of the back and finally led to unmistakable symptoms. In all of the cases the spinal fluid showed increased protein, xanthochromia, or complete block, and it is probable that the puncture should have been undertaken for diagnostic purposes at a much earlier date.

An examination of the roentgenograms of the spines showed that in all 3 there were definite changes of the pedicles which if properly assessed in the first place would have at least suggested the true nature of the complaint.

The 3 case reports are submitted and are carefully documented; they should be found useful to those who are interested in this subject.

SYMPATHETIC NERVES

Zadikoff J. J., and Grayce, I.: A Case of Carotid Sinus Syndrome Relieved By Operation. *Clin. Proc. Cape Town* 1945 4 253

The carotid-sinus syndrome is one of the causes of syncope, and recently there has been a tendency to deal with this condition by non-surgical methods. This article contains a brief review of the pertinent literature on the subject and describes a case in which the patient was relieved by surgical measures.

Electrocardiographic changes were noted during pressure on the hypersensitive right carotid sinus of the patient. A bradycardia of 44 per minute was produced by pressure on the sinus and at least one asystole lasting 2½ seconds was recorded. No attempt was made to make preoperative tests with atropine or to novocainize the bifurcation of the common carotid artery. A penarterial sympathectomy was performed from 2 inches below the bifurcation to 2 inches above it; thus the three carotid vessels were stripped for at least 2 inches. The patient had no further attacks of syncope and pressure on the affected sinus did not result in any consequential changes 6 months after the operation.

The authors believe that surgical intervention has a distinct place in the treatment of this syndrome and that it must be considered in all cases of syncope. The diagnosis rests on the ability to reproduce the syndrome by pressure on the sensitive sinus.

ADRIEN VERBRUGHEM M.D.

Hines, E. A. Jr. and Christiansen N. A.: Raynaud's Disease among Men. *J. Am. M. Ass.* 1945 129 1

The occurrence of Raynaud's disease in men is reported in a series of cases dating from January, 1930 to December, 1942 at the Mayo Clinic. The average incidence has been 21 per cent in males and 79 per cent in females. The authors stress the importance of accurate criteria in making the diagnosis of Raynaud's disease.

Raynaud's phenomenon is described as the occurrence of intermittent episodes due to a functional vascular disturbance either primary or secondary resulting in color changes of the extremities—principally the fingers and toes and less frequently the nose and ears. These episodes are initiated by exposure to cold, and less frequently by nervous or emotional strain and stress. When the condition is primary it may be referred to as Raynaud's disease.

A working basis for the diagnosis of this condition has been set forth in a previous publication by Allen and Brown, and is summarized as follows:

- 1 Episodes of Raynaud's phenomenon excited by cold or emotion
- 2 Bilaterality of Raynaud's phenomenon
- 3 Absence of gangrene or if it is present its limitation to minimal grades of cutaneous gangrene
- 4 Absence of any primary disease which might be causal such as occlusive disease of the arteries cervical rib or organic disease involving the nervous system
- 5 Symptoms of 3 years or longer duration

Symptoms in this series were reported as appearing as early as the age of 5 years and as late as 63 years. In 91 per cent of the cases exhibiting Raynaud's phenomenon the symptoms were recorded as having been present for 3 years. In 59 per cent the symptoms were present for 6 years and in 11 per cent they were present for 31 years or longer. The early establishment of a correct diagnosis of Raynaud's disease is emphasized; this condition is considered more benign than the more serious diseases which have Raynaud's phenomenon as a secondary manifestation such as thromboangitis obliterans, arteriosclerosis obliterans and scleroderma.

The treatment depends upon the degree of incapacitation, and conservative therapy is recommended when the disease is not too incapacitating. The patient should avoid exposure to cold or sudden changes of temperature, and should use warm, protective clothing. The direct relationship of tobacco to this condition is not clear but it is advised that

patients with this condition abstain from the use of it.

Sympathectomy was done in 3 cases, with prompt relief.

A detailed study of 100 unselected cases among 181 male patients was made; further studies were conducted on 69 of whom 33 per cent, having had conservative treatment, showed improvement, 41 per cent were unchanged, and 23 per cent were worse.

HOWARD A. BROWN, M.D.

MISCELLANEOUS

Nadler S. B.: Paroxysmal Headache. *J. Am. M. Ass.*, 1945, 159, 334.

Eight cases of paroxysmal temporal headache are reported; they were treated surgically. Characteristic attacks started with periodic throbbing pain in the right, left, or both temporal regions, radiating to the frontoparietal and postauricular areas. Gastrointestinal manifestations were frequent during the attacks.

Digital compression on the temporal artery on the affected side abolished the throbbing pain and the greater part of the continuous dull headache. The area in which digital compression afforded maximum relief was injected with 5 c.c. of 1 per cent procaine hydrochloride and this afforded complete relief to the majority of the patients.

Ligation and section of the temporal artery was then performed under general anesthesia, with reported relief of headache varying from 3 to 11 months after operation at the time of this report.

HOWARD A. BROWN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Schle, E.: On the Prognosis of the Papilloma of the Lactiferous Ducts. *Acta chir scand.* 1942 87 417

There has been a very considerable disagreement among pathological anatomists as to whether papilloma of the lactiferous ducts is benign or malignant. Some authorities hold that as many as 50 per cent of these papillomas develop into cancer while others maintain that it has never been proved that they represent precancerous conditions.

The only practical way to settle the question is to re-examine patients who have had papillomas of the lactiferous ducts and on whom only local extirpation of the tumors has been performed. With this object in view the author examined 53 patients on whom operation had been performed for this form of papilloma. Amputation of the breast had been performed in 26 of the cases however and these were not considered in his study. In the 27 other cases local extirpation had been performed. In 8 of these cases histological examination showed very marked atypia of the cells while in the 19 others the cells were only moderately atypical. A number of microphotographs showing the histological findings are given. Re-examinations were made after from 2½ to 8 years and only 1 case showed a recurrence. This had appeared after 4½ years and was benign the picture being that of papillomatous adenoma.

The author concludes therefore that it is not too great a risk to remove a papilloma of the lactiferous ducts by local extirpation. This spares an organ that is of great importance to the patient both physiologically and esthetically. It is advisable however to keep the patient under medical observation for a year or two after operation so that any recurrence may be detected early. AUDREY G. MORGAN M.D.

TRACHEA, LUNGS, AND PLEURA

Gusterson F. R.: Postoperative Chest Complications Controlled Study in Hernia and Meniscectomy Operations. *Lancet*, Lond., 1945 249 431

Two hundred soldiers were operated upon in a military hospital in the course of 2 years by practically standard procedures and under practically identical conditions—100 for hernia and the other 100 which were included in this study merely as controls, were subjected to meniscectomy. In each of these two groups 50 of the patients were given ether anesthesia and the other 50 were given gas-oxygen. For the ether the Oxford vaporizer was used which admits of a light, uniform administration the nitrous oxide and oxygen were administered in a closed circuit no suboxygenation being allowed.

All patients were examined the day before operation with special attention to the smokers cough reported by Morton (*Lancet* Lond., 1944 1 368). When the subjects had a history of recent coryza, they were not operated upon for at least a week after the symptoms had subsided. Those with a history of chronic bronchitis with sputum or with any chronic respiratory disease such as mild emphysema were all classed as having major preoperative respiratory complications, even though there were no signs of active disease. Early exercises were insisted upon and the stay in bed was 14 days in all cases. During the first 7 days the temperatures were recorded every four hours. The number of times a patient vomited was recorded by observation not by the patient's statements.

It was found that following herniorrhaphy temperatures from 99 F to 101 F inclusive developed in 14, 21 and 7 cases done under ether anesthesia, and in 15, 22 and 6 cases done under gas-oxygen anesthesia. Eight of the patients operated upon under ether and 7 under gas-oxygen developed temperatures of over 101 F. Of the patients subjected to meniscectomy, none developed a temperature of more than 101 F. 5 under ether anesthesia but none under gas-oxygen, developed temperatures of 101 F. Twenty three under ether and 28 under gas-oxygen developed temperatures of 100 F and 22 each under ether and under gas-oxygen had temperatures of 99 F.

Thus, it was found that in neither series was the incidence of chest complications any higher whether ether or gas-oxygen anesthesia was used. There was a higher incidence of preoperative chest complications (43 minor 7 major) in the hernia series than in the meniscectomies (15 minor 2 major), the number of cases developing major chest conditions was roughly doubled following herniorrhaphy irrespective of the anesthetic agent, which suggested a distinct liability to postoperative chest complications in the cases of hernia. However in no case were the full classical signs of lobar atelectasis found perhaps because treatment (see original article) was instituted at once. The presence of such a high incidence of preoperative chest complications in cases suggesting a liability to postoperative chest complications does, however, emphasize the need of a careful survey of each patient before operation and the fact that reliance must be placed on the careful postoperative routine rather than on the choice of any particular technique of anesthesia if the incidence of postoperative chest morbidity is to be reduced.

The incidence of postoperative vomiting was studied under the impression that patients who did not vomit were more liable to develop a chest condition, and the only postoperative difference which could be attributed to the anesthetic was found to

be a slightly higher incidence of postoperative vomiting after ether.

The author concludes from this study that the use of ether as an anesthetic does not increase the incidence of partial collapse of the lung or of any other chest complication following hernia operations, provided only the lightest necessary plane of anesthesia is maintained.

JOHN W. BRADY, M.D.

Aronovitch M: Medical Treatment of Postoperative Pulmonary Atelectasis. *Canad Med Ass J* 1945 53 2

Postoperative atelectasis is still the most important acute collapse of the lung which may occur. Its treatment properly consists in prevention. This entails proper preoperative hygiene of the nose and throat and the careful selection of cases for surgery. Very important however is the immediate postoperative care which is usually administered by the anesthetist and usually consists of carbon dioxide inhalations and the aspiration of mucus from the nasopharynx, throat and deeper structures if necessary.

In spite of all precautions pulmonary collapse will still occur in a certain proportion of cases. The immediate cause of the collapse is conceded to be a plug of mucus or fibrin and mucus which seals one of the larger or smaller bronchi. The contributing factors to this event may be many and accordingly various theories have been advanced to explain why this plug should occasionally occur.

No matter how the bronchial plug is formed the result is the same. Air in the alveoli distal to the plug is absorbed and collapse of these alveoli occurs. The clinician is then confronted with a patient who exhibits the familiar picture of postoperative atelectasis with its fever, shallow respirations, cyanosis and chest pain.

The problem is to remove the plug. Once this is gone the affected alveoli will usually re-expand and all symptoms disappear. Bronchoscopic aspiration can of course be done and must always remain as the final method of choice when others fail, but it is usually unnecessary to resort to this measure which is in itself an operation.

Sometimes exceedingly simple procedures such as a slap on the back, encouraging a hard coughing spell, or posturing the patient will dislodge a bronchial plug. Often however these measures fail and in such cases a more detailed knowledge of the mechanics of the bronchial tree may aid in rational therapy.

Once the plug firmly in the bronchus and atelectasis has occurred it may be assumed that there is a great deal of spasm. Indeed it is this bronchial spasm which probably contributes greatly to the shallow respirations and cyanosis seen in these cases.

Bronchospasm is an important factor which must be considered and must be eliminated in any rational treatment.

Another important fact which must be considered is the dry, viscid nature of the plug.

Two other factors must be considered. One is gravity but a more important factor is the intra-bronchial pressure proximal and distal to the plug. Atelectasis having taken place by absorption of the air distal to the plug, intra-bronchial pressure and pressure from the surrounding structures will tend to drive the plug in deeper. An expulsive force to drive the plug out of the bronchus should therefore be considered.

An attempt can be made to remedy each of these factors and the resultant combined action is often successful in curing the atelectasis.

It is not expected that the plug itself once formed, can be easily liquefied but if the bronchial mucosa can be made to secrete a thin watery fluid this will surround the adherent plug and the latter will then tend to float off. One-half ounce of mixture of ammonium chloride every 4 hours is helpful in achieving this objective.

The most powerful agent in relaxing the bronchial musculature is adrenaline. Ephedrine is satisfactory, however. Given hypodermically in a dosage of 1/4 gr. it has proved very efficacious. The bronchial dilator is best given some time after the expectorant so that bronchial secretion is already present. Twenty minutes or thereabouts should be allowed between the oral expectorant and the hypodermic bronchodilator which is repeated every 4 hours.

Gravity and expulsive force can now be called in to aid in the expulsion of the plug by posturing the patient and encouraging him to cough for some 10 minutes after the bronchodilator is given. This is to be repeated hourly. This method will not succeed in all cases but it is well worth a trial. If it fails and the patient has no relief after 24 hours bronchoscopic aspiration can always be done. There is no risk in delaying bronchoscopic aspiration for this length of time even if the patient is somewhat uncomfortable provided the possibility of lung suppuration can be minimized. Adequate prophylactic doses of sulfathiazole or sulfadiazine should therefore be given with this therapy.

Statistics are presented for which this method is employed at the Montreal Military Hospital. The good results.

JOHN E. KIRKPATRICK, M.D.

Kay, E. B. and Meade R. H., Jr: Penicillin in Infections of the Lungs and Bronchi. *J. A. M. A.* 1945 29 300.

Kay and Meade treated 93 patients having chronic infections of the lungs and bronchi with penicillin. Forty five of these patients had bronchiectasis, 17 had lung abscesses, 6 had suppurative pneumonitis, 19 had chronic bronchitis and 5 fungous infections.

Penicillin is of unparalleled value in the treatment of acute pulmonary infections but as chronicity develops it becomes less effective. Chronicity in pulmonary infections introduces factors not found during the acute stage, which influence the efficacy of penicillin therapy. They are the mechanical factors of tissue destruction, fibrosis, vascularity and bronchial occlusion.

Penicillin appears to be of value in the treatment of acute exacerbations of chronic infections superimposed attacks of bronchopneumonia, chronic bronchitis, minimal bronchiectasis and advanced bronchiectasis too widespread for pulmonary resection. It is also of value in preparing the patient for operation as an adjunct to surgery making possible operative intervention otherwise impossible and in decreasing the postoperative complications.

Penicillin is of no permanent value in the treatment of advanced bronchiectasis nor should pulmonary resection be withheld when indicated because of the false sense of security resulting from temporary benefit.

In the treatment of pulmonary suppuration, chronic lung abscesses and fungous infections the chief value of penicillin is its ability to decrease the general manifestations of toxicity to promote symptomatic improvement and to prepare the patient for operative intervention.

The intratracheal administration of penicillin in the treatment of chronic bronchitis and bronchiectasis appeared to give more benefit in many cases than intramuscular administration. As much as from 30,000 to 50,000 Oxford units of penicillin can be applied daily in one application to the tracheobronchial tree. Excellent results were obtained in patients with chronic bronchitis and minimal bronchiectasis by the use of this method.

STEPHEN A. ZEFMAN M.D.

Randolph V. S.: The Drainage of Cavities in Bilateral Pulmonary Tuberculosis. *J. Thorac. Surg.* 1945 14 395

In bilateral pulmonary tuberculosis the treatment of cavities is often the most serious problem and it is frequently insurmountable. Many patients with bilateral disease have been successfully treated with bilateral artificial pneumothorax. It is often necessary to sever adhesions on one or both sides of the chest in order to make the collapse successful.

When pneumothorax cannot be used because of too extensive adhesions it is necessary when considering other forms of collapse to study the patient from the standpoint of preserving adequate lung space. In the treatment of cavities at or very near the apex, bilateral extrapleural pneumolysis and extrapleural pneumothorax have rarely been employed successfully. In exceptional cases in which sufficient lung space may be saved bilateral thoracoplasty has been employed.

However if the cavity to be treated lies in the lower part of the upper lobe, a middle lobe, or the upper part of the lower lobe, these collapse methods are not available because collapsing the cavity will also collapse too much useful lung. In these cases some type of cavity drainage must be used. Open drainage of tuberculous cavities has ordinarily been disastrous but by the use of closed catheter drainage many cavity closures have been reported, however in many cases there has been a reopening of the cavities after the original closure.

In 2 cases of bilateral pulmonary tuberculosis which were not suitable for any form of collapse therapy the Eloesser flap drainage was used. In both cases the results were excellent. The field of this operation is definitely limited. It has hitherto been used on only one side of the chest when it has been possible to control the tuberculosis on the other side. However it may be of value for use on both sides of the chest. This form of drainage has the advantage of being a simple procedure and one which does not require close continuous aftercare.

SAMUEL KAHN M.D.

Thomas, J. W., Van Orstrand H. S., and Tomlinson C.: The Treatment of Bronchiectasis with Chemotherapy and Allergy Management. *Ann. Int. Med.* 1945 23 405

An evaluation by follow up examination and questionnaires was made of 75 cases of bronchiectasis treated by sulfonamides and or allergic management. In 13 of these cases operations had been recommended but they had been refused or postponed the remaining cases had been considered non-surgical because of minimal or advanced disease age and general conditions. The periods of observation varied from 4 months to 5 years, the majority of the cases being observed for 2 years at least, most of the patients had had the disease 5 years or longer.

In 57 cases, lipiodol bronchography and bronchoscopy established the diagnosis while in the remainder of the cases the diagnosis was made by means of the history, physical examination, absence of tubercle bacilli and fungi in the sputum and stereoscopic and plain chest films (which are at best only suggestive evidence). In one half of the cases the nonhemolytic streptococcus, streptococcus viridans and the hemolytic streptococcus were found, one fourth showed the pneumococcus and some showed the fusiform bacillus, spirochaeta, neisseria, catarrhalis, staphylococcus albus and haemophilus influenzae. Fifty five of the patients had associated major respiratory allergy including bronchial asthma, perennial allergic bronchitis and severe perennial allergic rhinitis.

Treatment consisted of palliative measures to reduce pulmonary infection to a minimum and to irradiate obstruction i.e. treatment of sinusitis and oral sepsis, rest, adequate diet and vitamins and postural drainage. Sulfonadiazine or sulfathiazole was used in most instances, the average courses were 7.7 gr. (0.5 gm.) four times daily for 4 weeks repeated from 0 to 9 times at intervals of from three to four months. Allergy management consisted of thorough investigation and avoidance of important offending allergens in the patients' environment, dietary restrictions, hyposensitization with extracts and autogenous vaccinations. These measures were followed for periods varying from 4 months to 3½ years.

The summary reveals the following results in addition to the preceding facts:

1. Twenty-three cases received sulfonamide drugs as the chief or only therapeutic measure. Twenty two of these showed definite improvement with reduction of cough and expectoration while under treatment.

2. Twenty-one cases were treated chiefly or wholly with allergy management. Fifteen of this group showed frank improvement with reduction in cough and expectoration.

3. In 31 cases combined allergy and sulfonamide therapy was used. Twenty-six showed at least from 25 to 100 per cent improvement in cough and expectoration.

4. Recurrences of symptoms of original severity were frequently noted following acute respiratory infections, cessation of allergy management, or in some cases when infrequent courses of sulfonamide drugs were used.

JAY BARTLETT, M.D.

Timney W. S., and McDonald, J. R.: Pulmonary Metastasis of Carcinoma Diagnosed by Bronchoscopy. *Minnesota M.* 1945 18 554

In 3 cases a metastatic lesion from carcinoma ulcerated through some portion of the tracheobronchial mucosa. The first case was probably an example of direct invasion of the trachea by carcinoma of the thyroid and the second case was an example of carcinoma of the breast with metastasis to the bronchial mucosa.

The third case was the most interesting one in this series. The metastatic lesion in the lung was diagnosed 3 years after nephrectomy for hypernephroma and there was no evidence of recurrence or metastasis 4 years after pneumonectomy for the metastatic tumor.

In all of these cases metastasis to the tracheobronchial tree was diagnosed on bronchoscopic examination and biopsy of tissue obtained bronchoscopically confirmed the diagnosis.

Griese, D. F., McDonald, J. R., and Giegert, O. T.: The Proximal Extension of Carcinoma of the Lung in the Bronchial Wall. *J. Thorac. Surg.* 1945, 14 362

This study was based on 55 cases of carcinoma of the lung in which the surgical specimens were examined microscopically to determine the proximal extension of the malignant lesion along the bronchial wall. Only 30 of the 55 cases were included in the final survey. In the remaining 25 cases the specimens had been mutilated by previous investigation or the carcinoma obviously did not involve a bronchus. The following types of tumor were encountered in the 30 cases: a squamous cell epithelioma in 16 or 53 per cent, an adenocarcinoma in 6 or 20 per cent, an adenoma in 7 or 23 per cent, and an anaplastic type of carcinoma in 1 case or 3 per cent respectively.

Although adenocarcinomas are considered more malignant than are squamous cell epitheliomas, the tumor had extended proximally in 10, or 62 per cent of the 16 cases of squamous cell epithelioma as com-

pared with 3 or 50 per cent of the 6 cases of adenocarcinoma. The adenocarcinomas however, extended a greater average distance proximally than did the squamous cell epitheliomas. Of the 16 squamous epitheliomas 5 were grade 2 and 11 were grade 3. Of the 6 adenocarcinomas, 1 was grade 2, 4 were grade 3 and 1 was grade 4. Proximal extension did not occur in the case in which the adenocarcinoma was grade 4. This is in agreement with the finding of New and Fletcher in cases of carcinoma of the larynx, and with that of Conway and Broders in cases of carcinoma of the urinary bladder, namely that carcinomas that are of grade 4 are not as prone to spread by direct extension as are those of grade 3.

There was no evidence of extension in the 7 cases of adenoma or in the case in which an anaplastic type of carcinoma was encountered.

In 8 cases extension occurred in the outer fibrous coat only. In 3, it occurred in the mucosal coat only; in 1 case it occurred in the submucosa and in 1, it occurred in both the submucosa and the outer fibrous coat.

When dealing with adenocarcinomas the surgeon should, if anatomically possible, sever the bronchus more than 3 cm. proximal from the gross limits of the lesion. If the tumor is a squamous cell epithelioma, a safe distance to sever the bronchus would be at least 1.5 cm.

Neuhof, H., and Stata, D.: Putrid Empyema without Foul Sputum. *Surgery* 1945 18 411

The diagnosis of putrid empyema in the absence of foul sputum or other evidence of a pulmonary abscess is difficult. The lesion should be suspected and efforts at diagnosis should continue as long as a given set of clinical manifestations are present. These consist primarily of outstanding and persistent chest pain, slight cough and expectoration, and an illness which is severe at least in the initial stage. Cough may be absent, the course may be chronic. The discovery of foul pus by aspiration of the pleura is the sole method of establishing the diagnosis. This discovery will often be a surprise. Wide drainage of the main lesion and its ramifications will effect a cure unless the diagnosis has been delayed too long. Although a pulmonary abscess is not demonstrable, a putrid pulmonary abscess is the precursor of "surprise" putrid empyema.

SHEPHERD A. ZIEGLER, M.D.

Collis, J. L., Davison, M. H. A., and Smith, P. R.: The Management of Traumatic Pyothorax. *Lancet, Lond.* 1945 245 778.

The 44 cases on which this article is based are instances of total or almost total pyothorax and do not include patients with early infected hemothorax. The high mortality of 27 per cent (12 cases) emphasizes the importance of this condition. The authors experience has led them to believe that a localized empyema is sometimes unavoidable, but that total pyothorax with the possible exception of cases associated with esophageal injury or very virulent

organisms such as the hemolytic clostridium welchii is an avoidable condition. In other words if pulmonary expansion is effected and maintained from the onset of treatment infection can produce only a localized empyema.

In cases of closed pyothorax aspiration is carried out for the first few days penicillin being introduced into the pleura after aspiration on alternate days. The aspirations may be necessary daily or on alternate days according to the rate of collection of fluid, and are followed every forty-eight hours by the introduction into the pleural cavity of 50,000 units of penicillin in 2 c.c. of water. At the last aspiration before drainage 20 c.c. of iodized poppy seed oil is introduced and posteroanterior and lateral roentgenograms are taken. A portion of the ninth or tenth rib is then resected, all clot removed and drainage instituted just under the lateral edge of the erector spinae. Breathing exercises are started at once. The incision is vertical for two reasons. The first is that it heals better this way if a horizontal incision is made serous fluid or pus can collect under the lower edge but if the incision is vertical outward drainage takes place more readily along the line of the incision. The second reason is that after a vertical incision is made it is easy to resect a portion of the rib one higher or lower if the first rib resection is found to be unsuitably placed. Although local anesthesia was used at first for these operations it has been given up in favor of cyclopropane.

A method of two-tube drainage with an additional apical tube allows the cavity to be washed out and prevents the drain from becoming blocked.

JOSEPH K. NARAY, M.D.

Hirschfeld, J. W. Bugge, C. W. Abbott, W. E., and Pilling, M. A.: Penicillin in the Treatment of Empyema. *J. Am. M. Ass.* 1945 128 577

Penicillin is a powerful antibacterial agent and almost nontoxic for man. It is not inhibited by pus or other products of tissue destruction. After intravenous or intramuscular administration penicillin penetrates poorly into collections of pus, but if it is injected directly into an abscess considerable concentrations persist for from 24 to 48 hours.

In order to effect a cure of pleural empyema by penicillin therapy alone the causative bacteria must be susceptible to penicillin, the empyema cavity must not be loculated nor contain pieces of necrotic lung or large clots of fibrin, a persistent bronchial fistula must not be present (because of constant re-infection of the cavity) and the lungs must be capable of re-expanding in order to obliterate the cavity. If the pleura becomes so thick that the lung cannot re-expand, operation is necessary in order to move the chest wall in to meet the lung.

Thirteen cases are reported. In spite of the instillations of 50,000 units of penicillin after aspirations several cases required rib resection. In 1 case, this was required because of the reappearance of pneumococci after three weeks of very intensive

penicillin therapy both intrapleural and intramuscular. In 2 other cases multiple bronchopleural fistulas prevented complete re-expansion of the lung and low grade fever persisted. In these cases penicillin considerably improved the patient's general condition and made rib resection a safe procedure. In a 2 year-old white girl, rib resection was performed because of lack of improvement after 6 days of penicillin therapy. This was followed by a rapid drop of temperature to normal and steady improvement. In another case infection of the chest wall following repeated aspirations made rib resection advisable.

Two patients in this series of 13 died as the result of empyema, 1 during the course of penicillin treatment and the other after rib resection. The immediate causes of death were pulmonary hemorrhage and multiple pulmonary infarcts respectively.

HEART AND PERICARDIUM

Lam, C. R.: Large Anomalous Vein (Left Vena Cava) Encountered in Operation for Ligation of Patent Ductus Arteriosus. *J. Thorac. Surg.*, 1945 14 393

During the course of operation on a patient suffering from a patent ductus arteriosus with subacute bacterial endocarditis a large anomalous vein was

Fig. 1. Schematic diagrammatic view of findings at operation showing the "left vena cava" being held away with the tape to expose the ductus arteriosus, which is in the curve of the aneurysm needle.

seen lying on the aorta, and following a course parallel to it. Its diameter was only slightly less than that of the aorta. Medially it disappeared into the areolar tissue of the mediastinum and appeared to enter the pericardium to the right of the aorta. It received at least one large branch from the neck. There was no pulsation or thrill in the vein and it collapsed with slight pressure.

Penitcut left superior vena cava has previously been reported but no mention has hitherto been made of a left inferior vena cava. The author believes that the simplest explanation for the vein in this case is to assume that it represents the left innominate vein and persistence of a left cardiac vein.

SAMUEL KATZ, M.D.

Urschel D. L., Bondy P. R., and Saitley S. M.: Acute Pericarditis. *England J. M.* 1945 233 399.

Eight cases of acute pericarditis were studied within three months at the Battery General Hospital, Rome, Georgia. The clinical x-ray and electrocardiographic alterations followed variable sequences in the different cases, variations incompletely described in textbooks. Since the diagnosis of acute pericarditis is often difficult, the authors present these cases to emphasize the variable sequence of x-ray, clinical, and electrocardiographic findings and also to demonstrate the relatively benign nature of certain cases of pericarditis when treated by modern methods.

Scott, Feil, and Katz, in 1929 first described the RS-T elevation occurring early in a case of hemopericardium and in one of purulent pericarditis, attributing it to myocardial ischemia produced by pressure. These changes indicate recent effusion or a gross effusion which will not allow further stretching of the pericardium. Foulger and Foulger, in 1930, showed that this change was temporary since the electrocardiogram returns to normal unless the intrapericardial pressure is maintained. Fowler, Rathe, and Smith in 1933 correlated the T wave changes in experimental pericarditis with the inflammatory reaction in the subepicardial myocardium. They also showed that when the myocarditis subsided and the inflamed area became fibrous the T waves returned to normal.

Bellet and McMillan, in 1938 showed that the elevation of the RS-T segment was transient and usually associated with rapidly developing types of pericarditis. Inversion of the T wave probably was associated with the subchronic stage and occurred when healing was taking place and the general toxemia was less. Vander Veer and Norris showed that the electrocardiogram might return almost to normal even though the infection and inflammation of the pericardial sac continued and the effusion increased. Elevations of the RS-T segment have not been observed in tuberculous pericarditis.

This series consists of 8 cases, all men between 2 and 27, 6 white and 2 negro. The causative organism was the tubercle bacillus in one case, the meningococcus in another, and the pneumococcus in the third case. The organism was presumed to be tuberculous in 2 cases and rheumatic in 3. These cases were studied by graphs correlating the heart size, the sum of the T waves, the elevation of the RS-T segments, the highest temperature daily, and the time of pericardial friction rubs (Fig. 1). The 8 cases are reported in detail.

Cases 1, 2, and 3, although caused by different etiological agents, graphically presented similar pictures. The heart increased rapidly in size at first, reaching its maximum at ten days. At this time there was little or no change in the electrocardiogram, although some elevation of the RS-T segment had occurred in cases 1 and 2. The maximum T wave inversion occurred in all 3 after the heart returned to original size. T wave inversion sometimes occurs after the temperature has returned to normal and the patient is clinically well. Cases 4 and 5 illustrated this. The T wave total in case 1 was positive throughout and a single electrocardiogram was typical of pericarditis. Only by repeated examinations could the characteristic picture be demonstrated on the graphic chart. This emphasizes the point that the diagnosis of pericarditis by means of electrocardiograms is frequently impossible without repeated examinations.

In case 4 the patient, presumably with tuberculous polyserositis, continued to run a low grade fever after 3 months of illness. The T wave showed a maximum inversion after the heart returned to normal size and remained inverted as long as the patient was under observation during which time the pericarditis continued to be active. In case 5, the T waves remained low for 9 months during which time there was clinical evidence of activity of the rheumatoid process.

Case 6, a severe rheumatic pericarditis, showed that the heart had reached its maximum size and, as returning to normal before the T waves reached their lowest point. The seventh case was the only one to show a maximum T wave inversion before the heart reached its greatest size. Early T wave inversion was followed by nearly isoelectric waves and then by more marked inversion. This rapid electrocardiographic alteration occasionally is seen in acute myocarditis secondary to rheumatic fever or myocardial infarction, but was not seen in the other cases studied. Possibly the early inversion may have been caused by rapidly accumulating fluid in a pericardial sac that could not stretch. This heart never became particularly large in spite of a severe degree of T wave inversion, and no evidence of cardiac tamponade appeared at that time. This patient was first seen on his sixtieth day of illness with a normal sized heart, no fever, T wave inversion, and normal white blood count and sedimentation rate. The T waves became upright in 4 weeks.

Case 8 followed a typical pattern for 3 months. The electrocardiogram showed a rapidly progressive increase in the T wave inversion till the twenty-ninth day. The inversion totaled 11.5 mm. and was

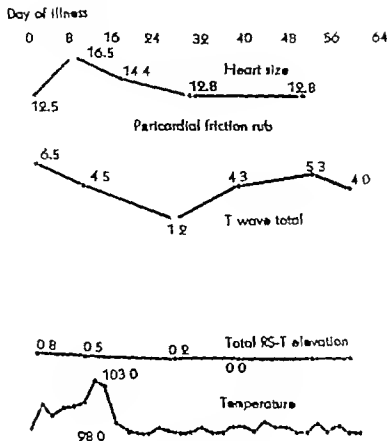

Fig. 1. Graph of findings in case 1.

the most marked in the series. From the twenty-ninth to the fifty-first day it decreased and then remained unchanged. The sedimentation rate was normal by the thirty-first day and the heart was normal by the thirty-eighth day.

The first change generally referred to in textbooks is the elevation of the RS-T segment. It was noted in 5 of 7 cases the highest being 2.0 mm. The change was transient and persisted from 6 to 30 days. It should be carefully searched for in every suspected case of pericardial inflammation since it is the first demonstrable change. However, normal persons may show this finding and therefore serial electrocardiograms are often necessary before an accurate diagnosis can be established.

In this series the maximum T wave inversion came between the sixteenth and forty-third days of disease the average time being the twenty-seventh day. This time interval is important since a patient with acute pericarditis may die long before diagnostic T wave inversion appears. Sometimes the T wave inversion does not involve all four leads and occasionally only one or two are inverted. There is usually some reduction in the total T wave deflection which can be shown by careful measurements in serial electrocardiograms.

In 5 cases the T waves returned to normal in an average of 59 days. In 1 case they remained low for 9 months. In another they remained inverted for 10 weeks and in a third case for 3 months. The authors

are not certain about the significance of persistent T wave inversion long after the temperature, pulse, chest x-ray film, white cell count and sedimentation rate have become normal. These changes may be similar to those in cases of myocardial infarction in which T wave deviations may persist for many months after the acute incident. The authors believe however that persistent inversion must be regarded with caution and for this reason they restrict the patient's activities until the T waves return to normal.

There was no consistent variation in the QRS amplitude although a lowered total deflection has been mentioned as a diagnostic sign in acute pericarditis.

The heart rapidly reached its maximum size in this series. In 2 of the cases the pericardium was tapped to demonstrate fluid. In all of the others there was a roentgenological diagnosis of pericarditis with effusion.

The pericardial friction rub appeared from the second to thirteenth day of disease in this series. It persisted for a period of from 4 to 16 days with an average of 9 days. Only 1 case failed to show a pericardial rub.

As judged from the cases observed there is no significant electrocardiographic difference in the pericarditis caused by rheumatic fever, tuberculosis or pneumococcal or meningococcal infection.

ROBERT R. BRIDGEMAN, M.D.

ESOPHAGUS AND MEDIASTINUM

Adams, R., and Hoover W B.: Benign Tumors of the Esophagus. *J Thorac. Surg* 1945, 4: 479

Benign tumor of the esophagus is a rare disease, when considered in terms of the total number of reported cases the frequency in respect to all esophageal tumors or the percentage of all patients with esophageal symptoms in whom the cause is a benign tumor. However these lesions comprise an important clinical group because they are readily curable by proper surgical management. They are interesting from the standpoint of differential diagnosis, prognosis and rarity and are a challenge to the surgeon who finds pleasure in detecting and correcting the bizarre ailment. The grand total known to us is 97 cases.

From 1933 to 1943 the percentage of cases diagnosed during life was higher, which is explained by the increasingly widespread use of the precision methods of diagnosis—fluoroscopy with barium and esophagoscopy. Also the number of cases discovered and recorded during the last 12 years is over one-half as large as the number of cases reported in the preceding 20 years. Three cases are reported in detail.

The symptoms of all esophageal lesions are so similar that they usually afford little differential diagnostic information. A small tumor rarely causes any symptoms and unless discovered incidentally in the course of fluoroscopic examination its presence ordinarily is not suspected until its size interferes with swallowing. In reviewing cases of carcinoma of the esophagus and the literature of benign esophageal tumors one is impressed with the frequency with which patients have been considered neurotic (globus hystericus) until they began to regurgitate solid food. Dysphagia appears much more slowly with benign tumors than with carcinoma. This is partly explained by the facts that the rate of growth as a rule is much less rapid, and that ulceration, while common and extensive with cancer is late and minimal with benign tumor. Case 3 illustrates the dramatic nature that symptoms may assume if torsion of the pedicle or trauma to the body of a pedunculated benign tumor induces venous obstruction and edema.

The 3 patients had no helpful physical signs but in all of them the roentgenological studies with barium brought out characteristic features of benign esophageal tumors. The walls of the esophagus appear elastic. Peristaltic waves pass through the tumor-bearing region. Even with a large intramural growth in one wall of the esophagus the wall directly opposite is covered with normal mucosa. As shown by the 3 intraluminal cases barium flows evenly around the tumors. As is evident in the roentgenograms in case 1 a thin stream of barium outlined each lateral margin of the growth with no break in the regular mucosal pattern, except at the upper margin of the negative intraluminal shadow where a film of barium seemed to be fitted as a cap over the superior tumor surface. One needs only to compare

these roentgenograms with similar ones showing the narrow, thick, irregular channel in the presence of a carcinoma in the same region to realize how definitely they differ in appearance.

The extirpation of each of these lesions presented some problems peculiar to location, pathology and the anatomy of the esophagus. In case 1 an intramural fibroma it had to be determined with certainty from which organ the tumor arose and after its localization to the wall of the esophagus, it was removed with preservation of an intact mucosa. In case 3 a pedunculated polyp an easy and safe endoscopic operation, instead of a hazardous external operation through the incised cervical esophagus, depended upon the suspension laryngoscope for good exposure and upon the electrocoagulating wire for reliable hemostasis.

In case 2 an intraluminal fibroma, the problem was somewhat more involved. The tumor was too large to be removed endoscopically and it was situated too low to be reached through an incision in the neck. Yet such a tumor must be removed with maintenance of the esophageal continuity or one must accept the alternative of an esophageal resection, cervical esophageal fistula, gastrostomy and external esophagoplasty with the multiple operations, mutilation, and frequent disappointment.

In order to avoid fatal postoperative mediastinitis, rigid asepsis and perfect healing must be achieved. As a contribution to the attainment of these ends, the esophagus should be defunctioned during the periods of preoperative esophageal sterilization and postoperative healing. Finally one must be able to operate in the upper posterior mediastinum, a region admittedly difficult of surgical access with the wide exposure prerequisite to palpatizing and aseptic technique. Each patient recovered without complication.

The literature of benign tumors of the esophagus is reviewed. Various diagnostic and technical problems arising in the management of such cases are discussed.

JOHN E. KIRKPATRICK, M.D.

MISCELLANEOUS

Titche, L. L.: Postbronchoscopic Reactions. *Am. Old. Rhinol.*, 1945, 59: 563.

The use of the bronchoscope for diagnosis and treatment of bronchopulmonary disease is well covered in the literature but there are a few articles emphasizing the harmful effects of this procedure.

Bronchoscopy offers a simple and direct means of investigating bronchopulmonary disease since a lesion of the parenchyma always results in changes of the mucous membrane of the draining bronchus. By watching these changes one can study the character and progress of lung lesions.

Bronchoscopy was performed by the author for diagnosis in cases in which the sputum was negative but the x-rays revealed tuberculosis, as a routine prethoracoplasty procedure, and for diagnosis and treatment of endobronchial tuberculosis. Broncho-

copy was employed for diagnosis in nontuberculous lesions and as part of the treatment of bronchiectasis and of asthmatic patients for the aspiration of secretions.

From January 1, 1943 to January 1, 1945, 361 bronchoscopies were performed on 214 patients. Two hundred and forty-five of these were for 147 tuberculous patients. Of this group, 103 showed a rise in temperature—91 during the first 72 hours and the remaining 12 up to the eighth postbronchoscopic day. This temperature rise varied from $\frac{1}{2}$ degree to 4.55 degrees. In 3 cases the elevation did not persist past the day of the procedure. In 36 the temperature returned to normal the next day, in 17 by the second day and in 15 by the third day.

In addition to this initial rise, 23 cases showed a secondary rise after the temperature returned to normal. In 16 cases this rise occurred between the ninth and thirteenth days following bronchoscopy. In 3 it occurred on the fifth day and in 1 case each on the seventh, eighth, fourteenth and fifteenth days. The temperature elevations ranged from $\frac{1}{2}$ to 6 degrees and lasted from 1 to 42 days. In 15 cases the temperature subsided within a week and in 5 others by the end of the second week. One patient had an elevated temperature until the forty-second day.

Of the patients with a secondary rise, 4 showed an extension of the disease in the lungs on x-ray examination. The author reports these cases in detail.

In attempting to see whether these reactions were caused primarily because the patients were tuber-

culous, the author studied the records of 67 patients with bronchiectasis, asthma, pulmonary malignancies, lung abscess or chronic bronchitis. A total of 116 bronchoscopies was done on this group and 37 showed temperature rises in the first week—32 of which occurred during the first 72 hours. This rise ranged from $\frac{1}{2}$ degree to 4 degrees. In 36 cases, the temperature returned to normal in 1 week and in only 2 of these was there a secondary rise in temperature.

The initial rise in temperature in a majority of instances is due to the trauma of instrumentation as evidenced by the similarity of the reactions in tuberculous and nontuberculous patients. The secondary rise in tuberculous patients is an important sign and appears to indicate a spread or activation of the disease. In the nontuberculous patients the secondary rise can be attributed to reactivation of the infection or to a secondary infection resulting from the instrumentation.

In order to prevent the further occurrence of these reactions, the author suggests a more careful selection of patients for bronchoscopy, a minimum of trauma during instrumentation and encouraging the patients to clear the tracheobronchial tree of secretions as soon as possible. Many believe that the disturbance of the cough reflex may be associated with the febrile response and extension of tuberculous disease. The author thinks that the minimum quantity of anesthetic necessary should always be used in order to disturb the cough reflex as little as possible.

ROBERT R. BROWNE, M.D.

sufficient reward. If the closure of the perforation causes too great a narrowing of the duodenum the addition of a gastroenterostomy is needed but other arguments in its favor such as relief from future ulcer symptoms, earlier feeding and obviating of future operation, seem unsound. The same probably holds true for excision and pyloroplasty. The patients on whom gastroenterostomy was done lived.

In many reports, gastric resection has shown the lowest mortality. Nevertheless, it is doubtful that this operation should ordinarily be given serious consideration. Gastrectomy is a highly technical operation which is not applicable for the average case treated under emergency conditions by the average emergency staff.

In conclusion the authors state that

1. It should be possible to lower our mortality. High mortality may be due to relative unfamiliarity with the surgical technique, to a delay in surgery until peritoneal infection has set in, or to a mistake in diagnosis resulting in the wrong approach with a consequent longer and less accurate operation. Leaving out age and other angles beyond our control, the time elapsing between perforation and operation is the most important factor affecting the results of the individual operator.

2. A correct diagnosis can usually be made as the clinical features are so striking as to make it apparent that a surgical emergency exists. In the great majority free air in the abdominal cavity can be shown by x ray if one wishes additional support.

3. While radical resection may have its place in selected cases in the best surgical clinics, the routine treatment should be the earliest possible and the simplest thorough closure with the best supportive preoperative and postoperative treatment.

4. Recurrence of ulcer symptoms will take place in the majority of patients. In the event of ulcer recurrence the proper medical treatment can be outlined and if surgery becomes necessary the best operation for the condition can be chosen after due deliberation and study and after proper preparation.

CHARLES BARON, M.D.

Urdondo, C. B. and Naslo, J.: The Incidence of Gastric and Duodenal Ulcer in Different Professions and Occupations (Incidenencia de la úlcera gástrica y duodenal en las profesiones y oficios). *P. curs. méd. argen.* 945, 32 38.

The authors have made a careful study of the profession or occupation of 2 557 patients with gastric and duodenal ulcers and give tables showing the details of their findings. These ulcers are more frequent among professional people than among physical workers and among all the professional people they are most frequent in public officials, probably because of the psychic demands made on them. A study of the cases in physical workers, in whom ulcers are less frequent than in psychic and intellectual workers, shows that gastric and duodenal ulcers are not caused by repeated microtrauma of the epigastric region as has frequently been claimed.

Among the professional people with ulcer there are many more male than female patients. The localization of the ulcer is related to a certain extent to the patient's occupation, duodenal ulcer being more frequent in professional people and gastric ulcer in workmen. Domestic work is classified as psychophysical and most of the patients in this group are women. They show a predominance of gastric ulcer.

A bad course of the ulcer is more frequent in professional workers than in workers of the physical and psychophysical groups. This also tends to disprove the theory that violence is involved in the causation of ulcer. A bad course does not seem to be related to sex or localization of the ulcer.

Recurrences were more frequent after one operation in the physical workers and after two operations in the professional workers. Among the few cases in which three operations were performed there were more physical workers with recurrences.

A hyperacid type of gastric secretion predominated in the physical workers, a normal acid curve in the psychic workers, and hypoacid or normal acid curve in the psychophysical groups. About 30 per cent of the patients showed some habit tending to cause alimentary intoxication, such as the use of tobacco, alcohol, mate, or coffee. The use of alcohol or tobacco was more frequent among the physical workers and of coffee among the psychic workers. The use of tobacco or mate did not seem to have any special tendency to cause ulcers.

AUGUST G. MORROW, M.D.

Dalley M. E., and Miller E. R.: A Search for Symptomatic Gastric Cancer in 500 Apparently Healthy Men of 45 and Over. *Gastroenterology* 1945 5 1.

The authors, in an attempt to discover minor (early) gastric malignancies, examined 500 normal men by a barium meal examination, the rationale being precisely that of a mass chest survey. All subjects were 40 years or over and were free of digestive complaints. All were examined by the barium meal procedure and fluoroscopy. A full gastrointestinal series was performed whenever a hint of abnormality was present.

The findings revealed that 3 men of 500 appeared to have persistent gastric lesions—one had a gastric ulcer, another a suspected antral polyp and the third had antral gastritis—the last being verified by resection.

While the authors' work was in progress, St. John Swenson and Harvey uncovered 3 gastric malignancies among 2,413 men and women. However the individuals in their survey were not necessarily asymptomatic. Rigler at the same time discovered in routine x-ray examination of the stomach 21 gastric cancers and 15 polyps among 217 patients with pernicious anemia.

The authors conclude that a survey of the general population in search of gastric cancer is not worthwhile but that studies of selected groups such as

persons with pernicious anemia should be expanded. On the other hand the rigid selection of candidates excluded individuals with the slightest symptoms and thus the results in no way detract from the view that even mild dyspepsia in older individuals demands a prompt and adequate investigation.

DOUGLAS R. MORTON M D

Waugh J M and Fahland T R: Total Gastrectomy. *Surg Clin. A. America*, 1945 35 903

In 77 cases of total gastrectomy by the abdominal route performed at the Mayo Clinic from 1917 to 1943 inclusive, the over-all surgical mortality rate was 44.3 per cent. The mortality rate for the 33 cases in which operation was performed between 1917 and 1939 inclusive was 60.6 per cent as compared with the mortality rate of 3.18 per cent for the 44 cases in which operation was performed between 1940 and 1943, inclusive. Gastrectomy was performed in 1943 in 20 cases with 5 deaths a mortality rate of 25 per cent.

Waugh and Fahland attribute the remarkable reduction of surgical mortality in this series to the increased experience of the surgeons in dealing with the procedure, improvements in postoperative care, the use of chemotherapy, and the early recognition and rigorous treatment of postoperative complications.

More than half of the patients who survived the operation of total gastrectomy for cancer lived 2 or more years whereas 2 patients who underwent total gastrectomy for benign lesions have lived 6 and 8 years respectively and are still alive as far as can be ascertained.

STEPHEN A. ZERMAN M D

Isaacs, A. H. Intussusception in Adults. *Surgery* 1945 18 457

Statistical data appear to show that of all intussusceptions, the incidence in adults is about 5 per cent. It is common medical experience that in infants there are, as a rule, no discoverable etiological factors, while in adults there is usually an organic lesion, a benign or malignant tumor as the basic cause. Other provocative influences are (1) typhoid ulcers (2) tuberculous ulcers, (3) dysentery (4) acute appendicitis (5) Meckel's diverticulum (6) a congenital ileal band (7) a submucous lipoma of the ileum (8) a foreign body (9) a sudden radical dietary change or (10) neoplasms.

Enlarged lymphoid patches not infrequently cause intussusception, and an instance in point appears to be the high incidence of the ileocecal variety with the presence of large Peyer's patches. The detrusor action of the terminal ileum and the greater size of the colon have been regarded as other probable causes.

The majority of intussusceptions are of the enterocolic variety and it is in the ileocecal zone that considerable anatomic alteration in the size of the gut takes place.

Fraser proved that the innervation of the ileocecal zone is distinctive in that the nerve supply of the ileum

is sympathetic and parasympathetic the cecum receives a supply of sympathetic nerves only. An explanation is thus found for the descending peristaltic irregularity.

Intussusception at times occurs during an attack of enteritis and there is a strong probability that the swollen Peyer's patches may induce the hyperperistalsis.

Intussusception of the gastrointestinal tract may take place anywhere between the stomach and the rectum. The large bowel is the most frequent site of involvement in adults because benign and malignant growths particularly the former are more common there than in any other part of the gastrointestinal tract.

An intussusception usually forms a rather firm sausage-shaped swelling composed of three concentrically arranged tubes or layers—the afferent, efferent, and encasing. The first two form the intussusceptum and meet at the apex or most distal part of the invagination. The encasing layer constitutes the intussusciplens and joins the returning layer at the neck of the intussusception.

Intussusception may be single or compound. In the latter the primary invagination is surrounded by a secondary one which may in turn be surrounded by a tertiary.

Three forms of intussusception may be distinguished:

1 Enteric (10 to 15 per cent) in which the small intestine invaginates is prevalent in older children and adults. It is usually of organic causation. In the ileocolic variety only the small intestine is involved it may progress to become an ileocolic variety ordinarily discoverable in children.

2 Colic (5 to 10 per cent) in which the colon encases (therefore, colocolic). This variety occurs in elderly persons. A not infrequent cause is a polypoid carcinoma or a benign polypoid growth.

3 Enterocolic (75 to 80 per cent) in which the ileum invaginates into the colon. This is common in infants.

When a gastroenterostomy has both an afferent and efferent jejunal loop the following three varieties of jejunojejunal intussusception may on rare occasions occur as complications within a few days or years after the anastomosis: (1) the afferent loop solely may intussuscept into the stomach (2) the efferent loop may retrograde and stop short of or pass through the gastroenterostomy stoma and (3) the afferent and efferent loops may intussuscept into the stomach.

In adults the symptoms of intussusception are not as prominent as in infants. They are vague in most instances, with signs of mild recurrent obstructions associated with symptoms of the provoking cause. There are colicky abdominal pains, nausea, vomiting, obstipation, and bloody stools. A mass in the abdomen is commonly not palpable. In jejunal intussusception symptoms, usually intermittent may be present for months or years. There is always a history of upper abdominal pain, especially after

meals. Nausea and vomiting are common. Blood in the stools is not as common in jejunal intussusception. The abdomen is not distended early but becomes manifestly so as the obstruction progresses. On auscultation exaggerated peristaltic sounds may be heard until there is complete obstruction when one elicits the significant silent abdomen. A tumor mass may be felt, with or without anesthesia. It is sausage-shaped and lies transversely across and subjacent to the abdominal wall.

The diagnosis is mainly roentgenographic or surgical.

If in a patient with a gastroenterostomy the afferent loop is intussuscepted the patient will as a rule complain of (1) postprandial epigastric pain with colicky exacerbations and (2) bilious vomiting. The roentgenograms in most instances will reveal a distended afferent loop. The opaque meal will demonstrate a rounded filling defect in the stomach (due to the intussusception) upon which a relief pattern, the jejunal plicae, will be observable. If the efferent loop takes a retrograde intussusceptal course an acute high small bowel obstruction results with consequent colicky abdominal pain and the vomiting of gastric, then bilious, and finally intestinal contents. If the afferent and efferent loops intussuscept into the stomach, an acute, high obstruction obviously results.

The differential diagnosis in intussusception must be made from (1) Henoch's purpura, (2) acute enterocolitis, (3) simple colic, and (4) tuberculous mesenteric glands.

The barium enema and examination of the abdomen without opaque media are used to diagnose intussusception. In subacute and chronic intussusception in adults, it will be found that the combined contrast meal and enema examination will prove most helpful in diagnosis.

Palliative treatment is justifiable only under the most exceptional circumstances. An early intussusception can sometimes be completely reduced with a pressure enema of water or air. This method is dangerous and is better employed in infants and older children. In early cases a barium enema may be given at low pressure and an attempt should be made to reduce the mass under fluoroscopic control. This is often surprisingly successful in the colic or enterocolic varieties. It is almost impossible to reduce the enteric variety merely by rectal injection.

As a rule, an immediate surgical operation should be performed as soon as the diagnosis is made. Either anesthesia is best avoided. Spinal anesthesia is preferred. A one-stage operation may be performed. When a hot pack fails to effect reduction an attempt should be made to insert a finger into the neck of the intussusception (between the entering and returning layers) and to sweep it around in this space. The adhesions are thus broken down and reduction facilitated. If this maneuver proves ineffective a rubber-covered forceps is placed in the neck as far as is safely possible and the blades are opened in several places. This procedure serves the dual purpose of

dilatating the neck and of breaking down recent adhesions. If the aforementioned methods fail, the neck should be divided for an inch or more along the antimesenteric border with a pair of forceps. The incision is closed transversely to avoid narrowing of the lumen of the gut.

If the large intestine is the intussusception site, graded operations are preferable. In some cases of irreducible uncomplicated intussusception a short circuiting operation may be performed. If the intestine is irreducible and gangrenous, one of the following expedients may be tried: (1) resection, with end-to-end, side-to-side, or end-to-side anastomosis, (2) Jescot's operation—removal solely of the invaginated part of the bowel through the encompassing part of the intestine. After the incision in the bowel is made, the invaginated part is withdrawn in a downward direction as far as possible and cut away. Circular suturing closes the cut margins of the amputated, gangrenous bowel. The caesarean part of the bowel is then approximated and united by a through-and-through continuous suture whereon a Lambert stitch is placed. Finally a few interrupted sutures close the neck of the intussusception.

The treatment of jejuno gastric intussusception is always surgical. If the afferent loop is involved, reduction is affected by slight traction. A recurrence is prevented either by anchoring the afferent loop to the stomach or to the transverse mesocolon or by undoing the gastroenterostomy. Sometimes a gastrectomy in part, including resection of the anastomosis, may be deemed advisable. If the efferent loop is entangled reduction by traction may be found adequate, but in delayed cases, with gangrene, resection must be carried out. When both intestinal loops are involved, reduction is by traction.

JOSEPH K. NARAY, M.D.

Segal, H. L., Scott, W. J. M., and Watson, J. S.: Massive Hemorrhage from the Small Intestine. *J. Am. Med. Ass.* 945, 29, 6.

As a result of the analysis of the authors' cases and of those reported in the literature the following suggestions are given to help differentiate massive gastrointestinal hemorrhage due to lesions of the jejunum and ileum from that due to gastroduodenal ulcers.

1. One should be aware that small intestinal lesions may produce this syndrome.
2. The pains present are not quite as typical as those of peptic ulcer.
3. Hematemesis is usually not present.
4. The gastrointestinal series is negative for a definite ulcer although it may be suggestive of duodenal irritability or pyloric spasm.
5. A roentgenological study should be made of the small loop for retained barium.
6. A Levine tube passed during the episode of melena will not reveal gross blood. (This is done after the barium meal has ruled out a gastric or esophageal lesion.)

7 A gastric analysis may show low values for hydrochloric acid.

8 The presence of a palpable mass which slides away from the fingers may suggest a lesion of the small intestine.

9 Small intestinal lesions may be present in addition to a peptic ulcer.

The possibility of a small intestinal lesion should be considered in any patient who has repeated or continuous melena in the absence of hematemesis and in whom the pains seem somewhat atypical for peptic ulcer. Such patients should have diagnostic studies even during the active phase to help determine whether the bleeding is from the common source peptic ulcer or from the uncommon origin in the small intestine. **JOHN J. MALONEY, M.D.**

Shallow, T. A., Eger, S. A., and Carty, J. B.: Primary Malignant Disease of the Small Intestine. *Am. J. Surg.* 1945 60 172.

Primary malignancy of the small bowel is a rare condition, which is difficult to diagnose early. The treatment of this condition requires extensive operative technique and results in a high operative mortality and grave prognosis. Since this is a challenge to the modern surgeon, the author reviews 38 consecutive cases of histologically proved small-bowel malignancy encountered in the Jefferson Medical College Hospital, Philadelphia.

Primary small intestine malignancy occurs in 0.2 per cent of all autopsies, while large-bowel malignancies are 36 times as frequent. Three per cent of all intestinal carcinomas and 60 per cent of all intestinal sarcomas occur in the small bowel. Each division of the small bowel is involved equally by malignancies, carcinoma being twice as frequent as sarcoma, however the frequency in the ileum is lowest for carcinoma and highest for sarcoma. Eger reports that of 305 duodenal carcinomas 62 per cent involved the second portion, 24 per cent the first, and 12 per cent the third, 2 per cent involved the entire duodenum. Small-intestine carcinoids comprise 0.03 per cent of the autopsy and surgical specimens (8.3% of all small intestine neoplasms). They occur chiefly in the ileum.

Small-intestine neoplasms are grossly classed in order of frequency as stenosing infiltrating or ulcerating and polypoid. Sarcomas extend toward the mesentery without producing obstruction or hemorrhage in contradistinction to carcinoma. Carcinoids are small firm submucosal yellow nodules which rarely obstruct, but grow slowly and metastasize to regional nodes in 25 per cent of the cases rarely to the liver. Thirty-one of the 38 cases showed metastases and extension to the regional nodes and liver. In 5 of the 7 cases of duodenal carcinoma there were widespread metastases; in 1 case there was regional node involvement and in 1 case there were no metastases. Of the 7 ampullary lesions 5 showed metastasis but in only 1 was the pancreas involved. Of the 14 jejunal and ileal malignancies 4 were without metastases, 9 had regional involvement, and 11

had widespread metastases. No malignant carcinoids were found.

The early diagnosis of primary malignancy of the small intestine depends on careful evaluation of the history and the physical laboratory and x-ray findings. The onset of symptoms was insidious in most of the cases although occasionally it was sudden with perforation, severe hemorrhage or intestinal obstruction. The duration of symptoms varied from 5 days to 7 days and averaged 7 months. Ampullary lesions produced biliary obstruction before intestinal obstruction, the occasional intermittency of the jaundice being due to tumor slough, increased intra-biliary tension which forced bile through the point of obstruction or subsidence of papillary edema. Over 75% of the small intestine neoplasms were palpable, fixed if duodenal and mobile if jejunal or ileal. Laboratory studies aid in diagnosis and guide the preoperative and postoperative management. Seventeen of 29 cases gave x-ray demonstration of the lesion. Vomiting caused several examinations to be unsuccessful. Eight neoplasms failed to visualize on x-ray even though the duration of symptoms averaged 14 months. In spite of this x-ray study seems to offer the best aid to diagnosis of these lesions at the present time.

Decompression of the intestinal tract and maximum improvement medically are essential preoperatively. This is accomplished by correcting any fluid and electrolyte imbalance, anemia, vitamin and plasma protein deficiency and impaired function of the heart, liver and kidneys. The type of operation depends on the patient's condition, the location and extent of the growth and the presence or absence of complications such as jaundice or metastases. Ideally early and adequate resection of the growth and the adjacent mesentery with re-establishment of bowel continuity is the treatment of choice.

Various operations were carried out. One duodenal malignancy was resected. It was located in the third portion, and a side-to-side duodenojejunosomy was carried out, the second portion of the jejunum just distal to the ampulla being anastomosed to the jejunum 10 inches from the ligament of Treitz. The patient was alive and well 10 months later.

In the ampullary group the bile was redirected to the gastrointestinal tract in all cases. Resection was contemplated in 2 cases without metastases but the patients failed to survive the first stage. All the jejunal lesions were resected and end-to-end anastomoses done. One case because of a contact carcinomatous fistula required a resection of the terminal ileum with an end-to-side anastomosis with the ascending colon. This case was reported in some detail by the author and 3½ months postoperatively showed normal x-ray studies of the small intestine and colon. One patient with a sarcoma invading the transverse colon is alive 12 years later. This was resected and anastomosed primarily. Another patient with sarcoma of the jejunum died of metastases fifteen years after the primary operation. Six

ileal malignant tumors were resected and 1 tumor was exteriorized, 3 which were considered nonresectable were treated with x ray therapy. Of the patients who underwent resection, 1 with lymphosarcoma is well 7 years later and the 3 others who survived operation could not be traced.

These surgical results compare unfavorably with large intestine malignancies. Since these lesions are difficult to diagnose and metastasize early, they are usually beyond the curable state at operation. The sarcomas have a better prognosis than carcinomas. The author believes that primary malignancy is most amenable to treatment if it is jejunal and least amenable if duodenal. The author treated 27 of his 38 cases surgically with a 43 per cent operative mortality. Four of the patients are living and well, 12 7 and 4 years and 10 months respectively after operation. Four others lived 5 4 and 3 years, and 1 year respectively. Sixteen survived 6 months or less, 3 were lost to follow up and 11 expired without surgery. The most common causes of death were metastases and circulatory failure.

ROBERT R. BIDDLE, M.D.

Kiefer, R. D. and Ross, J. R.: Chronic Ileitis. *J Am Med Ass* 945 39 94.

On the basis of the experience reported here with the treatment of 103 cases of chronic ulcerative enteritis, conservative management is indicated in the early acute forms of the disease. In mild cases of chronic uncomplicated terminal ileitis and in uncomplicated segmental enteritis with extensive involvement of the jejunum and ileum.

As a general rule, chronic terminal ileitis is best treated surgically. This is in agreement with the conclusions of Ginsburg and Garlock. When the enteritis is complicated by obstruction, fistulas or abscesses, surgical measures are definitely the treatment of choice.

Although surgery is not successful in all cases, the resection of the inflamed loops of intestine produces a high percentage of satisfactory results. Another point favoring surgical measures is the low operative mortality.

JOHN J. MALONEY, M.D.

Gatewood, J. W.: Solitary Diverticulitis of the Cecum. *Ann Surg* 945 57.

The difficulty of differentiating acute appendicitis preoperatively and carcinoma at operation, from the usual findings in the case of an inflamed cecal diverticulum makes a consideration of this subject of prime importance. The most common preoperative diagnosis made in cases of solitary diverticulitis of the cecum is appendicitis, while in many cases at operation, radical resections are carried out on a presumptive diagnosis of carcinoma. The possibility of solitary diverticulitis of the cecum should always be considered on examination of a patient who has had a previous appendectomy and who complains of right lower quadrant pain. When operating for appendicitis and finding an apparently normal appendix, one should make a careful search

for cecal diverticulitis. Two cases of solitary diverticulitis of the cecum occurring in young males are reported.

In most cases of solitary diverticulitis of the cecum, local excision is all that is required to effect a permanent cure. This is in contradistinction to multiple diverticulitis for which most treatment is palliative. As pointed out by Jones very large, inflamed diverticula lying close to the ileocecal valve, or between the leaves of the mesentery so as to jeopardize the cecal blood supply, require extensive resection. In the 3 cases reported one of the most distinguishing features at operation was the normal condition of the bowel surrounding the inflamed diverticulum, which made firm closure easy after local excision of the diverticulum. Associated appendectomy with local excision of the diverticulum is justified and does not increase the risk appreciably. In 1 of the cases microscopic examination of the appendix revealed a diffuse inflammatory process which might have caused trouble if it had been allowed to remain.

JOHN L. LINCOLN, M.D.

Dennis, C.: Ileostomy and Colectomy in Chronic Ulcerative Colitis. *Surgery* 945 8 435.

It has been found that with prompt and proper surgical management, chronic ulcerative colitis is not a disabling disease. Surgical management is recommended for all cases of nonspecific ulcerative colitis except the very mild ones that can usually be handled medically. The emergency indications for surgery are uncontrollable hemorrhage, fulminating disease, impending perforation, and obstruction. Four elective indications for surgery are recognized, cases that resist all forms of medical treatment, segmental ulcerative colitis, very early ulcerative colitis and polyposis including the cases with possible malignancy. From the satisfactory results obtained, and until the true nature of the disease shall have been discovered, surgery appears to offer the best hope to the patient.

During 16 recent months at the University of Minnesota Hospitals, Minneapolis, 23 cases of ulcerative colitis were observed, 16 were given the benefit of surgery and of the 7 not undergoing operation, 2 died, 2 improved, and 3 failed to improve.

The author stresses the fact that extreme thoroughness and precision in every detail of the preoperative, operative and postoperative care are the important factors that have made surgery for chronic ulcerative colitis a success at the University of Minnesota Hospitals. The procedures used to minimize the risk of surgery and to avoid the most complications that have made ileostomy objectionable are excellently described in full detail.

After careful preoperative preparation, ileostomy is the initial surgical procedure and should not be complicated by any other simultaneous procedure. A method of ileostomy which minimizes the complications of herniation, fecal fistula and prolapse is described. With meticulous postoperative care

excoriation and breakdown of the skin have been negligible.

The success of meticulous management of these patients is emphasized by the fact that in 20 cases there were 1 case of prolapse, 2 cases of recession, 2 cases of some trouble with skin excoriation, no cases of failure of primary union, no hernias and 3 deaths. The deaths occurred from pulmonary embolus in one case and from involvement of the ileum, jejunum, and stomach in the other. Colectomy is not done until from 4 to 6 months after the ileostomy and except in selected cases then only for repeated exacerbations of colitis, polyps or carcinoma of the colon, profuse drainage or continued bleeding.

The rectum is spared in removing the colon and an improved method of closing the rectal stump is described. In some cases it was possible to re-establish the continuity of the bowel by ileoproctostomy many months after the ileostomy.

DAVID H. LYNN, M.D.

Rubenstein, A. D. and Johnson, B. B.: Salmonella Appendicitis. *Am J M Sc.* 1945 210 517

It is probable that a significant reservoir of salmonella infection exists among the general population.

The authors studied 811 cases of salmonella infection, 20 of these (approximately 2.5%) developed signs and symptoms of acute appendicitis, and 18 came to operation. All of the cases in which the symptoms of appendicitis occurred were in children or young adults. The difficulty of the differential diagnosis in cases in which these maladies are associated is stressed.

Of the 18 cases which came to operation, 11 showed no acute inflammation while 7 were found to have acute, subacute, or gangrenous appendicitis. It is assumed that lymphoid hyperplasia of the small intestine, appendix, or mesenteric nodes was responsible for the acute abdominal manifestations.

The authors suggest that an underlying salmonella infection should be suspected in instances of unexplained persistent postappendectomy fever. They further point out that the recognition of the basic etiology in cases of salmonella appendicitis will aid in the prevention of secondary infections among contacts in the hospital and at home.

DAVID H. LYNN, M.D.

Hoerr, B. O.: Mortality Factors in Acute Appendicitis. *Surgery* 1945 18 303

The failure of improvement in the mortality figures for patients with acute appendicitis at the Peter Bent Brigham Hospital, Boston, Massachusetts, from 1913 through 1940 stimulated a detailed study of the 106 fatalities during this period. Attention was focused on the 80 operative cases in which death was directly attributable to progressing appendicitis or its specific complications.

Delay in operation was shown to be the major factor in fatal cases. Sixty-seven of the 80 patients

were operated on 48 hours or more after the initial symptom. Fifty-eight patients were operated on within 6 hours after reaching the hospital, but hospital delay of more than 6 hours occurred in 16 cases because of the uncertainty of the diagnosis. It is suggested that operation be performed promptly when the differential diagnosis lies between acute appendicitis and some other condition, such as acute salpingitis, in which operation is not definitely contraindicated. The consequences of delay are reflected in the fact that at the time of operation 53 patients had acute perforated appendicitis, 14 had appendiceal abscess, and only 13 had acute unruptured appendicitis. There were only 6 fatalities in the cases of patients who were operated on within 30 hours of onset of the condition. Of these, 5 had perforated appendicitis. It must be noted that 49 of the 80 patients had definitely received cathartics.

Fifteen patients had undrained residual abscesses at the time of death. The author states that such abscesses should be especially sought for in cases not improving after a period of 2 weeks from the onset of the disease. Ten patients died of severe ileus or mechanical intestinal obstruction, prompt preventive measures or timely operative intervention might have saved some of them. Three patients died despite adequate dosages with sulfonamides.

Statistics based upon the 80 cases give a slight advantage for the McBurney incision. Statistics, likewise, vindicate the trend in recent years toward closure without drainage, even in selected cases with perforation.

SAMUEL KAHN, M.D.

Hurt, L. E.: The Surgical Management of Colon and Rectal Injuries in the Forward Areas. *Ann Surg* 1945 122 392.

Initial surgery of 39 injuries of the colon and rectum was performed by a general surgical team of an auxiliary surgical group functioning with the Fifth Army in Italy. Most of the injuries were caused by fragments. Twenty-nine patients were operated upon within 12 hours of injury, 3 within 6 hours. A short time interval can contribute toward an increased mortality because more of the severely wounded come to surgery. The average time interval was 15 hours. The contribution of shock toward an increased mortality was exemplified by 5 deaths in spite of vigorous replacement therapy among 8 patients admitted in severe shock. The second part of the duodenum was injured in 2 of 4 cases of injury of the hepatic flexure. Peritoneal contamination and early infection responded gratifyingly to forward surgery and its adjuncts, sulfonamides and penicillin for only 12 patients exhibited objective signs of peritonitis. Eight patients sustaining injuries of the colon or rectum above were treated successfully. Thirteen with colon injuries complicated by severe concomitant wounds died a mortality rate of 33 per cent. Severe shock, secondary to injuries of the colon complicated by concomitant wounds, was the dominant cause of death. Next to shock, sepsis was the leading cause of death.

For obvious reasons primary suture of the unprepared colon in the presence of peritoneal contamination has always been condemned in the author's theater. Consequently all initial operations were designed to divert the fecal current outside the peritoneum. The only exception to this rule has been in those patients sustaining injury between the sigmoid and the extraperitoneal rectum. These perforations were closed by suture and supplemented by proximal colostomy. The type and severity of the injury occurring between the terminal ileum and sigmoid colon usually determined whether a loop or double-barrelled colostomy with spur was to be performed. Single or closely associated multiple anterior and lateral wall perforations and antimesenteric hemisections were exteriorized as loop colostomies. Mesenteric hemisections, transections, and extensive injuries necessitating resection of the colon were exteriorized as a double-barrelled colostomy with spur. In an endeavor to perform an initial operation that not only diverted the fecal current extraperitoneally but also left the patient with a simple stoma which could be closed secondarily without entrance into the peritoneal cavity. Since the extraperitoneal closure of a loop colostomy of the right colon is impractical, a single perforation of the right colon was treated by tube colostomy or cecostomy.

Injuries of the splenic flexure and left half of the transverse colon complicated by those of the left diaphragm and left lung caused by a single missile, were operated upon transdiaphragmatically. Some of the advantages of a thoracic operative approach in thoracoabdominal wounds on the left side were excellent visualization of the wound tract, easy removal of the frequently fragmented spleen, mobilization of the splenic flexure under direct vision, and elimination of the separate celiotomy incision, with its subsequent pain, which permitted the institution of an intensive cough routine so necessary for the postoperative intrapleural injury.

Before closure of the diaphragm the injured segment of the splenic flexure or transverse colon was exteriorized either as a loop or double-barrelled colostomy with spur through a stab incision in the left upper quadrant of the abdomen. Likewise, if drainage of the abdomen was desired the drains were brought out through another but smaller stab incision of the left abdominal wall. On the other hand, injury of the hepatic flexure complicated by injuries of the liver, right diaphragm, and right lung and caused by a single missile necessitated thoracotomy and a separate celiotomy incision as the liver offers complete obstruction to exploration of the right abdomen.

The initial surgery of extraperitoneal perforations of the rectum consisted of thorough debridement of the wound tract, suture of perforations, and sigmoid colostomy. In addition, resection of the coccyx and incision of the fascia propria were done to insure adequate drainage of the retroperitoneal, posterior and pararectal spaces. All sigmoid colostomies were of the loop type. However a recent personal com-

munication with surgeons in Base Hospitals has revealed that loop colostomy for rectal injuries has failed in many instances, to divert completely the fecal current. Consequently patients with rectal injuries have arrived at the Base from the Forward Area Hospitals with fecally contaminated buttock wounds and the rectum filled with feces. In the future it is proposed to transect the sigmoid and prepare a spur at the time of initial operation of all extraperitoneal rectal injuries.

Colcock has reported from a hospital in the Zone of Communication that osteomyelitis of the sacrum has been a frequent complication of coccygectomy in those with rectal wounds. Because of this, posterior drainage is now being accomplished without resection of the coccyx. It is the feeling of most of the surgeons in this theater that adequate drainage can be ensured through a curved incision inferior to the coccyx, incision of the fascia propria, and opening of the posterior and pararectal spaces by blunt dissection.

JOHN E. KIRKPATRICK, M.D.

Croce E. J. The Management of War Injuries of the Extraperitoneal Rectum. *A. & S. Surg.* 215, 408.

Injuries of the rectum present many problems which are peculiar to it alone. These problems arise largely from its physiological and anatomic properties. As the organ of temporary storage and evacuation of the solid wastes of the intestinal tract, its contents teem with organisms, many of them potential pathogens, both aerobic and anaerobic. Anatomically it is for the most part unprotected by infection resisting peritoneum. It traverses a tissue which is highly vulnerable to infection, and it is difficult of surgical access. In order to understand more fully the implications of the anatomic problems, the essential details of the relationships of the rectum are reviewed.

The clinical syndrome of retroperitoneal abscess was a nightmare to the surgeons of World War I. Drummond reviewed the problem at the close of World War I. His suggestions as to treatment reveal that the problem at that time was still very much in the experimental stage, although some of his suggestions have proved extremely practical.

In extraperitoneal wounds of the rectum the only hope of success lies in very free local drainage carried out at the earliest possible moment. With a view to establishing efficient drainage he removed the uninjured coccyx in a cases, and in addition arranged for free drainage of the wounds of entry and exit. He found by stripping up the bowel that he was able to expose the wound in the rectum and was thus enabled to drain and pack off the surrounding parts and prevent further tracking by retroperitoneal hemorrhage.

During the past 3 years the authors were fortunate enough to administer definitive treatment to a moderate number of patients returning from the battlefields in various stages of convalescence from war wounds of the rectum, and in addition, were able to

evaluate the treatment of many others who had not remained under their care. From these observations it was believed that progress has been made during this war in the management of extraperitoneal injuries of the rectum and that it warranted the crystallization of surgical management. The part played by surgical prophylaxis in contrast to the supportive measures of blood plasma, and chemotherapeutic agents is emphasized. When the latter are applied alone without surgery they may influence the early mortality rate in assisting recovery from shock, but they do not appreciably alter the morbidity or late mortality rate from chronic sepsis. These measures have been proved to be merely adjuncts and not in any way substitutes for early and properly executed surgery.

The following conclusions as a result of observations have been reached:

1. Perforation of the intraperitoneal portion of the rectum results in fecal contamination of the cellular tissue of the intraperitoneal space. This space communicates with the retroperitoneal space posteriorly over the sacrum and this may result in full unloading and widespread sepsis behind the peritoneum.

2. Even when the perforation cannot be located but there is presumptive evidence of its presence or potential development from contusion or infarct of the rectum as judged from the course of the missile and the presence of a large hematoma in the intraperitoneal space, an effective sigmoid colostomy should be established at once.

3. A sigmoid colostomy alone will not prevent infection of the intraperitoneal space although the infection is likely to be less widespread and fulminating after contact with the normal intraluminal pressure is severed and gross contamination of the normally functioning bowel is avoided. In addition, the intraperitoneal perirectal space must be ascertained by coccygectomy and loosely packed.

4. Mere sacralization of the perirectal space while life-saving and prophylactic against spreading retroperitoneal sepsis is not however complete ideal treatment. Unless the perforation is located and closed a persistent fistula may develop.

JOHN E. KIRKPATRICK, M.D.

Dixon, C. F. and Benson, R. E. Carcinoma of the Sigmoid and Rectosigmoid Involving the Urinary Bladder. *Surgery* 1945 18 191

At present carcinoma of the sigmoid and rectosigmoid with distant metastasis is amenable only to palliative treatment. However when local extension of the disease only is present the condition is seldom inoperable. It therefore seemed advisable to the authors to point out some of the problems associated with carcinoma of the sigmoid and rectosigmoid involving the urinary bladder and to review their experiences with its surgical management. This study is based on 64 consecutive cases in which operation was performed by the senior author in the years 1931 to 1943 inclusive.

A small amount of secondary invasion of the urinary bladder by carcinoma of the sigmoid or rectosigmoid may give rise to no clinical or laboratory findings. More extensive involvement often produces distressing urinary symptoms and pyuria.

Of the 64 patients in the present series, 59 were males and 5 were females. The apparent infrequency of involvement of the urinary bladder in this condition in the female in comparison with the male is evidently attributable to anatomic differences in the pelvis. The ages of the 64 patients varied from 39 to 76 years the average age being 55 years. In the majority of cases carcinoma had been present for a long time and it is therefore not surprising that many patients were in poor general condition.

Probably the first step in invasion of the urinary bladder by carcinoma of the sigmoid or rectosigmoid is an inflammatory attachment of the tumor to the peritoneal covering of the bladder. This situation sometimes is encountered at operation. In such a case the malignant process can be dissected from the urinary bladder without an opening into its lumen. The examination of small bits of tissue from the vesical wall at the site of attachment will reveal the presence or absence of residual carcinoma and will allay any doubt in the surgeon's mind as to whether the malignant process has been completely eradicated. The inflammatory reaction around a secondary malignant growth of the bladder is a phenomenon not only of the early stages but also of the later stages of the malignant disease. Often advanced carcinoma that has extensively infiltrated the wall of the bladder is surrounded by such a severe inflammatory reaction that it is difficult to determine even at operation when the lesion is in full view and can be examined by the palpating hand whether the reaction is primarily inflammatory or neoplastic.

When a large carcinoma in the sigmoid or rectosigmoid has extended to the urinary bladder and is surrounded by an indurated inflammatory reaction the surgeon may be tempted to perform colostomy and to wait several weeks for the inflammation to subside before undertaking resection of the bowel. Undoubtedly this is often a valuable procedure but the senior author recently has concluded that postponement of resection after the distal segment of colon has been defunctionalized will not as a rule appreciably diminish the inflammatory reaction if the malignant growth has penetrated completely through the wall of the bladder. In such instances the urine and the diseased condition of the bladder continue to feed the infection in spite of the use of urinary antiseptics. Therefore it has become the senior author's practice to resect such lesions primarily whenever the general condition of the patient warrants the procedure.

In 45 of the 64 cases in this series the condition was classified as operable. Two patients in the group who presumably had removable lesions died after colostomy. In the remaining 40 cases resections were performed. In 19 of the 40 cases the

For obvious reasons, primary suture of the unprepared colon in the presence of peritoneal contamination has always been condemned in the author's theater. Consequently all initial operations were designed to divert the fecal current outside the peritoneum. The only exception to this rule has been in those patients sustaining injury between the sigmoid and the extraperitoneal rectum. These perforations were closed by suture and supplemented by proximal colostomy. The type and severity of the injury occurring between the terminal ileum and sigmoid colon usually determined whether a loop or double-barrelled colostomy with spur was to be performed. Single or closely associated multiple anterior and lateral wall perforations and anti-mesenteric hemisections were exteriorized as loop colostomies. Mesenteric hemisections, transections and extensive injuries necessitating resection of the colon were exteriorized as a double barrelled colostomy with spur. In an endeavor to perform an initial operation that not only diverted the fecal current extraperitoneally but also left the patient with a simple stoma which could be closed secondarily without entrance into the peritoneal cavity. Since the extraperitoneal closure of a loop colostomy of the right colon is impractical a single perforation of the right colon was treated by tube colostomy or cecostomy.

Injuries of the splenic flexure and left half of the transverse colon complicated by those of the left diaphragm and left lung caused by a single missile were operated upon transdiaphragmatically. Some of the advantages of a thoracic operative approach in thoracoabdominal wounds on the left side were excellent visualization of the wound tract, easy removal of the frequently fragmented spleen, mobilization of the splenic flexure under direct vision and elimination of the separate celiotomy incision with its subsequent pain, which permitted the institution of an intensive cough routine so necessary for the postoperative intrapleural injury.

Before closure of the diaphragm, the injured segment of the splenic flexure or transverse colon was exteriorized either as a loop or double-barrelled colostomy with spur through a stab incision in the left upper quadrant of the abdomen. Likewise, if drainage of the abdomen was desired the drains were brought out through another but smaller stab incision of the left abdominal wall. On the other hand, injury of the hepatic flexure complicated by injuries of the liver, right diaphragm and right lung, and caused by a single missile necessitated thoracotomy and a separate celiotomy incision, as the liver offers complete obstruction to exploration of the right abdomen.

The initial surgery of extraperitoneal perforations of the rectum consisted of thorough débridement of the wound tract, suture of perforations, and sigmoid colostomy. In addition resection of the coccyx and incision of the fascia propria were done to insure adequate drainage of the retroperitoneal, posterior and pararectal spaces. All sigmoid colostomies were of the loop type. However a recent personal com-

munication with surgeons in Base Hospitals has revealed that loop colostomy for rectal injuries has failed in many instances to divert completely the fecal current. Consequently, patients with rectal injuries have arrived at the Base from the Forward Area Hospitals with fecally contaminated buttock wounds and the rectum filled with feces. In the future it is proposed to transect the sigmoid and prepare a spur at the time of initial operation of all extraperitoneal rectal injuries.

Colcock has reported from a hospital in the Zone of Communication that osteomyelitis of the sacrum has been a frequent complication of coccygectomy in those with rectal wounds. Because of this, posterior drainage is now being accomplished without resection of the coccyx. It is the feeling of most of the surgeons in this theater that adequate drainage can be ensured through a curved incision inferior to the coccyx, incision of the fascia propria, and opening of the posterior and pararectal spaces by blunt dissection.

JOHN E. KIRKPATRICK, M.D.

Croce, E. J.: The Management of War Injuries of the Extraperitoneal Rectum. *Ann. Surg.* 1945 408.

Injuries of the rectum present many problems which are peculiar to it alone. These problems are largely from its physiological and anatomic properties. As the organ of temporary storage and evacuation of the solid wastes of the intestinal tract, its contents teem with organisms, many of them potential pathogens both aerobic and anaerobic. Anatomically it is for the most part unprotected by infection resisting peritoneum. It traverses a tissue which is highly vulnerable to infection, and it is difficult of surgical access. In order to understand more fully the implications of the anatomic problems, the essential details of the relationships of the rectum are reviewed.

The clinical syndrome of retroperitoneal sepsis was a nightmare to the surgeons of World War I. Drummond reviewed the problem at the close of World War I. His suggestions as to treatment reveal that the problem at that time was still very much in the experimental stage, although some of his suggestions have proved extremely practical.

In extraperitoneal wounds of the rectum the only hope of success lies in very free local drainage carried out at the earliest possible moment. With a view to establishing efficient drainage, he removed the injured coccyx in a cases, and in addition arranged for free drainage of the wounds of entry and exit. He found by stripping up the bowel that he was able to expose the wound in the rectum and was thus enabled to drain and pack off the surrounding parts and prevent further tracking by retroperitoneal hemorrhage.

During the past 5 years the authors were fortunate enough to administer definitive treatment to a moderate number of patients returning from the battlefields in various stages of convalescence from war wounds of the rectum and in addition, were able to

evaluate the treatment of many others who had not remained under their care. From these observations it was believed that progress has been made during this war in the management of extraperitoneal injuries of the rectum and that it warranted the crystallization of surgical management. The part played by surgical prophylaxis in contrast to the supportive measures of blood plasma and chemotherapeutic agents, is emphasized. When the latter are applied alone, without surgery, they may influence the early mortality rate in assisting recovery from shock, but they do not appreciably alter the morbidity or late mortality rate from chronic sepsis. These measures have been proved to be merely adjuvants and not in any way substitutes for early and properly executed surgery.

The following conclusions as a result of observations have been reached:

1. Perforation of the infraperitoneal portion of the rectum results in fecal contamination of the cellular tissue of the infraperitoneal space. This space communicates with the retroperitoneal space posteriorly over the sacrum and this may result in fulminating and widespread sepsis behind the peritoneum.

2. Even when the perforation cannot be located but there is presumptive evidence of its presence or potential development from contusion or infarct of the rectum as judged from the course of the missile and the presence of a large hematoma in the infraperitoneal space an effective sigmoid colostomy should be established at once.

3. A sigmoid colostomy alone will not prevent infection of the infraperitoneal space although the infection is likely to be less widespread and fulminating after contact with the normal intraluminal pressure is severed and gross contamination of the normally functioning bowel is avoided. In addition, the infraperitoneal perirectal space must be saucerized by coccygectomy and loosely packed.

4. Mere saucerization of the perirectal space while life-saving and prophylactic against spreading retroperitoneal sepsis is not, however, complete ideal treatment. Unless the perforation is located and closed a persistent fistula may develop.

JOHN E. KIRKPATRICK, M.D.

Dixon, C. F., and Benson, R. E. Carcinoma of the Sigmoid and Rectosigmoid Involving the Urinary Bladder. *Surgery* 1945 18 191.

At present carcinoma of the sigmoid and rectosigmoid with distant metastasis is amenable only to palliative treatment. However when local extension of the disease only is present the condition is seldom inoperable. It therefore seemed advisable to the authors to point out some of the problems associated with carcinoma of the sigmoid and rectosigmoid involving the urinary bladder and to review their experiences with its surgical management. This study is based on 64 consecutive cases in which operation was performed by the senior author in the years 1931 to 1945 inclusive.

A small amount of secondary invasion of the urinary bladder by carcinoma of the sigmoid or rectosigmoid may give rise to no clinical or laboratory findings. More extensive involvement often produces distressing urinary symptoms and pyuria.

Of the 64 patients in the present series 59 were males and 5 were females. The apparent infrequency of involvement of the urinary bladder in this condition in the female in comparison with the male is evidently attributable to anatomic differences in the pelvis. The ages of the 64 patients varied from 29 to 76 years, the average age being 55 years. In the majority of cases carcinoma had been present for a long time, and it is therefore not surprising that many patients were in poor general condition.

Probably the first step in invasion of the urinary bladder by carcinoma of the sigmoid or rectosigmoid is an inflammatory attachment of the tumor to the peritoneal covering of the bladder. This situation sometimes is encountered at operation. In such a case the malignant process can be dissected from the urinary bladder without an opening into its lumen. The examination of small bits of tissue from the vesical wall at the site of attachment will reveal the presence or absence of residual carcinoma and will allay any doubt in the surgeon's mind as to whether the malignant process has been completely eradicated. The inflammatory reaction around a secondary malignant growth of the bladder is a phenomenon not only of the early stages but also of the later stages of the malignant disease. Often advanced carcinoma that has extensively infiltrated the wall of the bladder is surrounded by such a severe inflammatory reaction that it is difficult to determine even at operation when the lesion is in full view and can be examined by the palpating hand whether the reaction is primarily inflammatory or neoplastic.

When a large carcinoma in the sigmoid or rectosigmoid has extended to the urinary bladder and is surrounded by an indurated inflammatory reaction, the surgeon may be tempted to perform colostomy and to wait several weeks for the inflammation to subside before undertaking resection of the bowel. Undoubtedly this is often a valuable procedure but the senior author recently has concluded that postponement of resection after the distal segment of colon has been defunctionalized will not as a rule, appreciably diminish the inflammatory reaction if the malignant growth has penetrated completely through the wall of the bladder. In such instances the urine and the diseased condition of the bladder continue to feed the infection in spite of the use of urinary antiseptics. Therefore it has become the senior author's practice to resect such lesions primarily whenever the general condition of the patient warrants the procedure.

In 43 of the 64 cases in this series the condition was classified as operable. Two patients in the group who presumably had removable lesions died after colostomy. In the remaining 40 cases resections were performed. In 19 of the 40 cases the

attachment to the bladder was of an inflammatory nature and removal of the tumor did not necessitate an opening into the lumen of the bladder. In the remaining 31 cases portions of the full thickness of the vesical wall were removed. In 15 of these approximately a third or more of the organ was resected. In 6 cases smaller segments were resected. In most of the cases resection of the bowel was completed by end-to-end anastomosis. There were 7 operative deaths. Twenty of the 40 patients were living at the time of follow-up or for more than five years after resection.

Hayden E. P.: *The Surgical Treatment of Carcinoma of the Rectum.* *N. England J. M.* 1945 833 8

Statistics on 198 cases of resection for carcinoma of the rectum are presented. In the presence of one or two metastases in the liver, or when the local growth, although extensive and perhaps abscessed, could still be removed, operation was completed in order to give relief if not cure, in this unfavorable group of patients. Of 217 patients explored only 19 presented a carcinoma so extensive that a radical procedure would have been foolhardy. One-stage abdominoperineal resection was performed in 131 cases. The other procedures carried out, in order of decreasing frequency were two-stage abdominoperineal resection, anterior resection, bilateral resection, end-to-end suture and tube resection.

A stay of from 3 to 5 days in the hospital before operation on the colon was usually an adequate period for general rest, preparation of the bowel, completion of laboratory work, and whatever measures seemed necessary to improve the patient as an operative risk. Unless contraindicated, postoperative spinal anesthesia, which greatly facilitates the ease of operation, was used. The colostomy was opened in 1 or 2 days and an enema given on the fourth or fifth day. Boric irrigations of the posterior wound were begun after removal of the posterior pack and continued until the discharge ceased. The average postoperative hospital stay of these patients was 5 weeks.

In the entire series there were 16 hospital deaths, a mortality of 13 per cent. The chief causes of death were pneumonia, sepsis, embolus and obstruction. Although over 50 per cent of the deaths occurred following one-stage resection, this should not be considered an indictment of the procedure, since actually, the number of deaths (14) was only 10 per cent of the number of single-stage resections (131), a mortality lower than that of the series as a whole. Of the 198 patients undergoing resection, 75 died later. In most cases of recurrent disease 75 of them died of unrelated causes and 96 are still alive. Of the 98 patients operated on over 5 years ago 38 or 39 per cent, have survived without evidence of disease for from 5 to 14 years. The longest interval before death occurred from recurrent disease was 3 years and 5 months after operation.

JOHN L. LINDQUIST M.D.

Mandl, F.: *The Technique and Results of the Primary and Secondary Pull Through Operations after Removal of Tumors of the Rectum and Rectosigmoid Surgery* 945, 18: 314.

Since the restoration of continence is of prime importance after the removal of tumors of the rectum and rectosigmoid, any radical operation which does not permit this possibility is regarded as imperfect. The techniques of the primary (Hochenegg) and the secondary (Weil) pull-through methods are described, the latter is accomplished by the artificial production of prolapse (Mandl) from the sacral anus and operation on the sacral hernia. The pull-through procedure may be used equally as well after sacral or abdominosacral radical operation. The method of Hochenegg holds the greatest promise of success for the restoration of continence after operations on the rectosigmoid.

Colostomy should precede the pull-through operation. Details are described. SAMUEL KARR, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Ruffin, J. M., and Wise, R.: *The Value of Plasma Vitamin-A Determinations in the Differential Diagnosis of Jaundice. A Preliminary Report.* *Gastroenterology*, 945 4-466.

It has been shown repeatedly that the plasma level of vitamin A is low in liver disease. This is to be expected since it is generally agreed that carotene is converted by the liver into vitamin A. Therefore, the authors present the hypothesis that if jaundice is due to common duct obstruction *without liver damage*, one would expect a normal vitamin A level in the plasma, whereas jaundice from a diffuse hepatitis should be accompanied by a low level of vitamin A in the plasma.

In every patient in the authors' series who was classified clinically as having acute hepatitis or catarrhal jaundice, there was a significant lowering of the plasma vitamin A. Since a gradual rise in these levels coincided with clinical recovery, serial determinations of vitamin A may have definite prognostic value. There was no constant correlation between the vitamin A levels and other tests of liver function except the cephalin flocculation test, which was positive in every case.

Of the 6 patients who were found at operation to have obstruction to the common duct, 6 had no demonstrable evidence of liver involvement and had vitamin A levels which were either within or close to normal limits. The levels were definitely lowered in the remaining 4 patients, but in each case either the duration of the disease or obvious infection were factors which could readily have resulted in liver damage. Thus it would seem that a patient with common duct obstruction of short duration, without evidence of liver involvement, probably will have a normal vitamin A level, whereas if the obstruction has been prolonged, or if there is evidence of biliary tract infection or metastases to the liver, the vitamin A

level may be reduced. On the other hand patients having a diffuse hepatitis invariably will have a definite lowering of their plasma vitamin A, and it may well be that this procedure will afford valuable evidence in distinguishing between these two forms of jaundice.

FARL O. LATIMER, M.D.

Eddy, J. H. Jr: Methionine in the Treatment of Toxic Hepatitis. *Am J M Sc* 1945 310 374.

Miller and Whipple have shown that there is increased sensitivity of the liver to toxins following protein depletion in dogs exposed to chloroform. Goldschmidt, Vars, and Ravdin, in their work on mice, pointed out the protective action of protein diets. Carbohydrate as a liver protector is generally accepted and Miller and Whipple believe that its effectiveness is primarily due to its sparing the protein stores.

Lately interest has centered on the identification of the specific protein factor responsible for liver protection. Miller, Ross, and Whipple in 1940 showed that methionine and to a less extent cystine would protect the liver against injury if given before chloroform anesthesia—this protection was comparable to the feeding of a large protein meal. In 1942 they showed this same protection occurred even when the methionine was given 3 or 4 hours after chloroform anesthesia, but 6 hours after anesthesia no protection occurred presumably because all of the cells had been fatally damaged. Therefore for methionine to be of any value some viable liver tissue must be present. Clinically then early treatment is essential if methionine is to be effective. Choline alone has been shown to be useless as a protecting agent but combined with cystine it rivals methionine. Goodell, Hanson, and Hawkins in 1944 poisoned dogs with mapharsen and demonstrated the effectiveness of methionine against this hepatotoxin.

It is believed by many that methionine protects the liver from damage primarily because of its sulfur content, since protein-depleted dogs are more completely depleted of sulfur. Heppel *et al* showed that there was decreased resistance among protein-depleted animals to dichloroethane but if they were fed methionine and choline there was increased resistance to its toxic action. These dogs showed no evidence of hepatic lesions and this suggested that the protective effect of methionine may not be dependent on the liver alone. To support this theory the authors showed adrenal changes in some of their animals.

Gyorgy in 1944 stimulated clinical interest in methionine. He outlined the progression of changes in animal livers on a protein deficient diet from fatty infiltration through necrosis to cirrhosis. He pointed out the presence of ceroid in the cirrhotic livers produced by dietary means a product not seen in other forms of animal or human cirrhosis. He compares the kidney lesions simultaneously seen in cases of damaged livers on a dietary basis with the so-called hepatorenal syndrome in man. Gyorgy sug-

gested that choline and cystine are needed for the synthesis of another substance that may be methionine. He recommends its use in the prevention and treatment of hepatic injury due to purely toxic as well as dietary factors.

The author in reporting cases of carbon tetrachloride poisoning noted that the severest cases all occurred in negro women with high fat and protein deficient diets. White women with the same job and adequate diets showed only mild toxic symptoms. A case report by Beattie *et al* of treating carbon tetrachloride poisoning with methionine stimulated the author's study of its use in the treatment of hepatitis due to trinitrotoluene and later other types of hepatitis and cirrhosis.

Since July, 1944 the author has treated 30 cases of acute toxic hepatitis with methionine. Most of them were due to T.N.T. and at least 10 patients were seriously ill. To date, there have been no fatalities as compared with the published mortality of from 30 to 35 per cent in T.N.T. hepatitis. Prior to the use of methionine the author treated 3 patients with T.N.T. hepatitis, 1 of whom died and the other has a prolonged illness. Many patients seen since then have appeared to be as severely poisoned as these first cases on admission.

The average length of hospitalization of the cases treated with methionine varied from 4 days to 7 weeks and averaged 13 days. The diagnosis was based on an analysis of the occupational exposure, physical examination, icteric index and Hanger cephalin flocculation test and urinalysis for urobilinogen and bilirubin. The daily urinalysis for urobilinogen and bilirubin is of value in following the patient's course. A decrease in the bile in the urine and an increase in urobilinogen is closely followed by a decrease in the icteric index. Below 20 this decrease is slow and often a value of from 10 to 12 persists for several months. The Hanger test never gives a false negative, and false positives are rare. The author does not believe that a reading of + or ++ is significant. This reading also returns to normal slowly and may not be negative for one or two months.

Almost all patients complained of dizziness, nausea, vomiting, weakness, and pain in the right upper quadrant. On physical examination they showed jaundice and palpable enlarged livers. There has been a preponderance of white males with this condition although both colors and sexes are affected.

Treatment included bed rest, a high protein and carbohydrate diet and a low fat diet, multiple vitamin products, additional B complex vitamins and the oral administration of methionine in doses of from 3 to 5 gm daily. The average dose was from 3 to 4 gm a day but in 2 cases with more jaundice the dose was increased to 8 gm daily and the patients were fed with a duodenal tube. Both cases improved markedly after 48 hours.

The author then presents abstracts of 3 of the more severe cases of T.N.T. toxic hepatitis. Two of these cases showed such remarkable improvement after the dose was increased that the author believed

the usual dose of methionine might be inadequate and that from 6 to 8 gm. daily should be given to all seriously ill patients. The author gave 12 gm. a day to 1 seriously ill patient without evidence of toxic reactions. The usual course is to start the patient on smaller doses and increase the amount if clinical improvement is not soon apparent.

Several cases of acute carbon tetrachloride hepatitis as well as 2 cases of epidemic hepatitis all of which were treated with methionine, were improved. The treatment of some cases of cirrhosis of the liver has been started, but no conclusions cannot be drawn from the few cases in which treatment has been completed. It is apparent, however, that methionine or choline plus cystine will be of value in early cirrhosis and in controlling episodes of acute activity in older cases. Little help can be given to the far advanced cases as the functional unit has been irreparably embarrassed by the laying down of scar tissue.

ROBERT R. BROZLOW, M.D.

Blumberg, N., and Zisserman, L: Acute Suppurative and Gangrenous Cholecystitis. *Am. J. Surg.* 94:5 to 38

Much has been written about acute cholecystitis. Experimental work suggests that the pathology is usually a mechanical obstruction of the cystic duct with edema and ischemia of the wall, followed by secondary infection. The question of immediate or delayed surgery in acute cholecystitis has long been controversial. Each policy has some disadvantages; the former commits the surgeon to operate in a septic edematous field and the latter submits the patient to the dangers of a lesion that may be progressive. Acute cholecystitis can resolve itself spontaneously without surgical interference or it may progress and terminate in gangrene or empyema. The authors present this article as a study of advanced gall bladder disease—empyema and/or gangrene with or without perforation.

A series of 82 cases were examined in the period from 1929 to 1944 at the Philadelphia Jewish Hospital. Thirty (37%) of these cases were males averaging 53.3 years of age. The 52 females averaged 55.9 years and the ages of all ranged from 20 to 72. The authors compare these figures with those in other reports published in the literature.

Fifty-four patients (66%) gave a history of symptoms referable to the biliary tract prior to the present attack, and only 6 definitely denied such symptoms. Many gave a history of gall bladder disease extending over a great many years.

The interval between the onset of the present attack of pain and its termination by operation or antecedent demise averaged 12 days for the men and 3½ days for the women. At this hospital, it was the policy to operate on acute cases only if it was deemed necessary because of a progressive lesion, and to wait for subsidence of the acute symptoms whenever feasible.

Abdominal pain in this series originated (1) in the right upper quadrant, (2) in the epigastrium, or (3)

as generalized abdominal pain. Fifty per cent of the patients reported radiation usually to the back, right shoulder or across the abdomen. Abdominal distention was not often noted but marked tenderness localized to the right upper quadrant was usually present. Nine patients reported a history of chills and fever with the present attack, and nausea vomiting or both were present in most cases. Only 10 specifically denied either of these symptoms. No consistent change in bowel habits was noted. Jaundice appeared in only 10 per cent of the patients during the present attack and only 1 per cent had a history of previous jaundice.

An enlarged mass in the upper right quadrant was definitely palpable on admission in 38 cases (46.3%). There was definitely none palpable in 35. The preoperative temperature was usually a sustained elevation sometimes as high as 103 degrees and other times barely elevated. A moderate temperature averaging about 101 degrees was usual. Blood pressure readings on admission varied widely but averaged 134/79 for men and 144/80 for women.

The average white blood count on admission was 15,600 cells per cubic millimeter for men and 15,870 for women (8.3% and 80.9%, respectively, were neutrophils). A great many of the patients showed a fall in the white blood count prior to operation, the males averaging 14,000 with 80.9 per cent neutrophils and the females 13,950 with 76.3 per cent neutrophils a day or so preoperatively. Since these cases were progressive with probably accompanying lesions this did not indicate an improvement in the pathological process. The red cell counts were quite normal in most cases with the exception of some concentration due to dehydration.

Fasting blood sugar tests were made on 61 patients 13 of whom were known diabetics. Levels less than 100 mgm. per cent were obtained in 30 cases (39% of the nondiabetic group). Nineteen (31% of the nondiabetics) had levels between 100 and 150. The remaining 12 nondiabetics had levels above 150.4 over 150. The somewhat elevated blood sugar levels were attributed to concomitant coronary occlusion, intravenous glucose therapy shortly before the test, and unrecognized diabetes mellitus. The authors believe there was nothing to suggest any tendency to produce an elevated fasting blood sugar as is known to occur in acute coronary occlusion. Blood urea nitrogen determinations in 63 cases were within normal limits in most cases.

An attempt to correlate the severity of the disease with clinical and laboratory data was considered inadvisable so the records of 2 cases of perforated gall bladders were studied separately. These cases represented 2.5 per cent of the entire group. They were not necessarily all recent perforations, some being well encapsulated by adhesions of omentum, and only 3 were associated with widespread peritonitis. Rupture into the duodenum occurred in 1 case.

The ages of the 9 men patients averaged 61.8 years and those of the 12 women 57.1 years, and nearly all

of the patients had an antecedent gall bladder history. Only 3 denied any prior biliary dysfunction. The average duration of the recent acute attack was 11 days for the females and 8 days for the males. The acuteness of the average perforated case was noted and earlier interference practiced 8 cases being operated within 7 days of the acute onset and 5 within 3 days. One third of this group had a palpable mass in the gall bladder region on admission to the hospital.

The pain of onset was diversified and more wide spread and the right upper quadrant pain and tenderness were more severe and more often present than in the general group. Two-thirds of the patients had extreme tenderness, abdominal rigidity, nausea and vomiting. The remaining one third consisted of cases in which the perforation was long standing with localized chronic abscess formation. These had very little tenderness or rigidity.

In the perforated group the admission white count averaged 16,600 with 83 per cent neutrophils. Three cases had counts in excess of 26,000.

Surgery of the gall bladder was performed in 73 cases (86% of the entire series). The operation varied from simple incision and drainage to complete excision according to the seriousness of the case. In approximately one half of the operative cases cholecystectomy was done. In the perforated group only 3 had cholecystectomies while 14 were treated by simple incision and drainage.

Spinal anesthesia was used in 59 (81%) of the operations. Supplementary anesthesia of nitrous oxide oxygen, ether or pentothal was used in 7 cases. Nine were done under local and 5 under general anesthesia and 14 of the perforated group were done under spinal and 3 under local anesthesia.

Stones were found in 65 patients (70%). In 11 cases they could not be definitely ascertained. Six cases definitely had none. Two-thirds of the perforated group had stones and only 1 definitely did not. The examination was not complete in the remainder.

Of the entire group of 81 patients, 20 died during their hospital stay. This group averaged 60 years of age. Of the 73 operative patients 11 died post-operatively a mortality of 15.1 per cent. Twelve of these patients died as a direct result of biliary disease, and 4 of causes uninfluenced by and unrelated to biliary disease.

In spite of the lessened trauma attending gall bladder incisions the mortality for this procedure was more than twice as much as for excision. For the most part the patients were poorer risks. In the mortality group the average interval between the onset of the attack and its termination by operation or prior demise was 10.5 days. The white count averaged 16,300 with 81.8 per cent of neutrophils.

There were 13 diabetic patients in the series (15.9% of the total) which correlates with the idea that diabetics have twice the tendency to develop gall stones. The average age was 61.4 years and 5 of these patients were males. One half were operated

on within a week, and 9 had palpable gall bladders preoperatively. The average white count was 15,200 with 81 per cent of neutrophils. Three cases perforated an incidence of 23 per cent. All these facts show a similarity between diabetic and nondiabetic cases. Eleven diabetics (85%) were operated on and 20 had gall stones. Two cholecystostomies and 3 cholecystectomies were done under spinal anesthesia. Seven diabetics (54% of the diabetics) died these deaths made up 35% of the total mortality. All of these deaths were due directly or indirectly to biliary disease.

The presence of gall stones in cases of acute cholecystitis in a far greater incidence than chance alone suggests points to a common etiology or to the fact that stones may play some role in the acute process. Since most patients have been suffering more or less from chronic gall bladder disease before developing an acute and dangerous condition, it may be wise to consider the prophylactic approach to the problem, i.e. the desirability of removing the gall bladder in all symptomatic cases of chronic cholelithiasis as a curative for symptoms and a preventive of complications. Certainly every case of acute cholecystitis that is allowed to subside should be operated on after a reasonable interval to preclude future more serious attacks.

The authors believe that the severity of gall bladder disease depends directly upon the chronicity of a gall bladder condition. The diminished vascularity with increasing age and the fibrosis accompanying attacks may favor widespread venous damage with sudden vascular occlusion.

It is recognized that it is not possible to correlate the severity of the signs and symptoms with the degree of disease present in any given patient.

Although there is a marked tendency for diabetics to form stones, there is no unusual tendency for the diseased gall bladders in these cases to progress to suppurative or gangrene. The exceptionally higher mortality in these cases suggests that tissue destruction in the gall bladder is tolerated as poorly as elsewhere. Diabetic patients should not only be considered poorer risks for surgery in advanced gall bladder disease, but probably deserve more prophylactic surgery. ROBERT R. BRADLOW, M.D.

Oster, G. F., and Dow, R. S.: Variations and Anomalies of the Biliary Duct System and Its Associated Blood Supply. *Rec'd J. S. S. G.*, 1945, 53: 316.

Dissection was carried out on 30 cadavers to show variations in the extrahepatic biliary duct system and cystic artery. The cystic and hepatic ducts may join at an acute angle (Fig. 1) or follow a long straight or spiral tortuous course (Figs. 2 and 3). Accessory hepatic ducts were found in 6 of the 30 cadavers. They may unite with the gall bladder with the cystic duct (Fig. 4) with the right hepatic duct (Fig. 5) with the common hepatic duct or come into the angle at the junction of the cystic and common hepatic ducts (Fig. 6). Frequent variations

Figs. 1 to 4. Variations in the extrahepatic biliary duct system and cystic artery. ACA, accessory cystic artery; CA, cystic artery; CBD, common bile duct; CD, cystic duct; CHD, common hepatic duct; GA, gastroduodenal artery; OB, gall bladder; HA, hepatic artery; LHA, left

hepatic artery; LHD, left hepatic duct; LPV, left branch of portal vein; PV, portal vein; RGA, right gastric artery; RHA, right hepatic artery; RHD, right hepatic duct; RRV, right branch of portal vein; SAV, superior mesenteric vein; SV, splenic vein.

occur in the common hepatic, and right and left hepatic arteries.

The cystic artery a very important neurosurgically showed a good deal of variation. It may be normal i.e. arise from the right hepatic to the right of the common hepatic duct (Fig. 7) but may originate behind (Fig. 10) or to the left of the duct. It may come from the left hepatic artery (Fig. 12) or from the gastroduodenal artery (Fig. 13). Accessory cystic arteries are rare. One was found arising from

the hepatic artery (Fig. 14) another from the left hepatic artery.

The amount of variability in the extrahepatic duct system and its associated blood supply makes it of the utmost importance that the surgeon secure satisfactory visualization of these structures at the time of surgery.

The 14 figures here included show the various findings of this study.

RICHARD J. BROOKETT, JR., M.D.

Van Gelderen, G. Transpapillary Duodenal Drainage of Hepatic Duct (Die transpapilläre duodenale Hepatikusdrainage) *Acta chir scand* 1944, 90: 27

Insertion of a T tube into the common duct is fraught with the danger of a secondary cicatricial stenosis the drainage leads to a considerable loss of fluids and ions and in addition, the absence of bile in the intestines interferes with the resorption of fats. Moreover the loss of undigested fats impairs the absorption of proteins and calcium. Finally a deficiency of the fat-soluble vitamins A, D and K may be the sequel of the external drainage of bile.

For all these reasons it has been suggested that external drainage of the common duct be replaced by choledochoduodenostomy. However such anastomosis facilitates the development of ascending cholangitis especially because the new stoma is deprived of a sphincter. Therefore this procedure should be employed only if the papilla cannot be stretched and if one suspects small stones in the hepatic duct.

A primary closure of the common duct is not advisable in the presence of acute cholangitis as a rule. The primary closure is certainly contraindicated if an induration of the head of the pancreas compresses the outlet of the common duct. In such instances an internal drainage of bile is desirable. A rubber drain buried in the common duct is not always expelled through the duodenum and may be responsible for a recurrent cholangitis or formation of stone.

To obviate these drawbacks, Voelcker introduced a drain through the common duct into the duodenum and exposed the tip through a transduodenal incision, the drain was pulled through the opening in the duodenum and carried to the outside through a Witzel's fistula. The drain could be removed within a few days without leakage of the bile or duodenal contents.

The author modified Voelcker's procedure in the following manner: bougies are introduced through a choledochotomy to dilate the papilla and a rubber drain is carried from the common duct into the duodenum through the papilla. An incision is made in the duodenal wall over the protruding tip of the drain and a lateral opening is made in the tubing to establish an internal duodenal bile drainage. The drain is pulled and carried through a Witzel's fistula. The incision in the common duct is closed with catgut and the gall bladder is removed. The drain is brought out through a stab wound in the abdominal wall and clamped with a hemostat. Approximately one week after the operation the drain can be removed. In this manner acute cholangitis is successfully combated without external bile drainage. The icterus does not disappear as promptly as after external drainage but, on the other hand, dehydration is avoided and the general condition of the patient improves rapidly.

Only the part of the drain directed from the lateral opening in the duodenal portion toward the liver

Fig. 1. a, Diagram of procedure. b Special drain about closed by interruption.

must be hollow while the remaining portion of the drain may be solid which avoids the necessity of a clamp.

The drain may be used not only in infected cases accompanied by high temperature but also in all cases in which a primary suture of the common duct does not appear dependable. The method is applicable also in patients with a chronic inflammatory induration of the head of the pancreas in whom it may replace a T tube or a permanent anastomosis. The author's drain may be employed also in reconstruction of the biliary ducts and after choledochoduodenostomy.

JOSEPH K. KARAT, M.D.

Peterson, L. W. and Cole, W. H.: Chronic Sclerosis of the Common Bile Duct Causing Complete Stenosis of the Common Bile Duct. *Arch Surg.* 1945 51: 25

Peterson and Cole wish to call attention particularly to the type of chronic pancreatitis associated with diffuse atrophy and fibrosis throughout the entire gland. Such a process may produce surprisingly little physiological or mechanical disturbance. However jaundice may develop and become permanent because of the severity of the sclerosing process involving the common duct.

While this condition is not common, the seriousness of destruction of the terminal end of the common duct by the progressive pancreatitis is sufficiently well appreciated that every effort should be made to treat acute pancreatitis early and eliminate it if possible. The etiological factor in the production of the usual type of acute edematous pancreatitis appears to be strongly related to cholelithiasis. The

fact that in some cases the pancreatitis subsides after cholecystectomy is suggestive proof of this relationship but it is by no means conclusive, since not infrequently cholecystectomy fails to stop the pancreatitis. Occasionally it develops after cholecystectomy.

Localized pancreatitis in the head of the pancreas, simulating carcinoma, is rather commonly observed by surgeons. The process which frequently produces complete obstruction of the common duct, usually subsides so completely within a few weeks or months that all symptoms disappear. The surgeon too often attributes the entire success of relief of obstruction to the short-circuiting operation, i.e., cholecystenterostomy.

Complete permanent obstruction of the common duct due to chronic pancreatitis is a difficult lesion to treat, but presents much less difficulty than obstruction due to complete absence or destruction of the common duct, because the remnant of the common duct simplifies the operative procedures. When the obstruction is due to localized pancreatitis involving only the head of the pancreas the prognosis for spontaneous complete recovery appears to be much better than when a generalized chronic sclerosing pancreatitis is producing a complete obstruction of more than transient type. Therefore, the customary operation of cholecystenterostomy for local pancreatitis in the head of the pancreas appears to be a logical procedure, particularly since the anastomosis will frequently remain open for only a few months at the end of which time the pancreatitis usually subsides completely with relief of the obstruction. The operation of cholecystenterostomy has one serious disadvantage namely the resulting development of cholecystitis and hepatitis which has been shown experimentally by Waggenster and others.

It is extremely difficult to differentiate chronic pancreatitis localized to the head of the pancreas and producing temporary complete obstruction of the common bile duct from carcinoma of the head of the pancreas without a deep biopsy from the lesion. In the even more rare type of diffuse chronic sclerosing type of pancreatitis operative therapy must be directed at establishing a permanent nonstenosing communication between the suprapancreatic portion of the common bile duct and the intestinal tract. In addition, the regurgitation of food and intestinal secretions must be prevented as much as possible.

Of the several operative procedures that have been described, each has some individual merit. The procedure of choice would be an anastomosis of the proximal stump of the common duct to the duodenum or an anastomosis of the proximal end of the common bile duct to the blind end of a single arm of jejunum utilizing the Roux principle. Into this blind loop of jejunum, through which food does not ordinarily pass, valves, as previously described, are placed to help prevent regurgitation of food. A side-to-side anastomosis has the added advantage of

allowing function of the terminal duct to be resumed if the pancreatic lesion should clear sufficiently to allow relief of the obstruction. If the terminal end of the duct is hopelessly destroyed, the duct may be mobilized and either a transplantation into the duodenum or an anastomosis performed. If the latter procedure is used, a vitallium tube may or may not be used, according to the size of the common duct.

BENJAMIN GOLDMAN, M.D.

Manninger S. R. and Dorody H. K.: Islet Cell Tumors of the Pancreas. *Surgery* 94:1, 18, 171.

The relationship of islet-cell tumors of the pancreas to hypoglycemia is now well recognized and there have been an increasing number of such cases reported in the literature of the last decade. Is Whipple's recent review on 149 cases of islet-cell tumor showing hypoglycemia there were 106 which were considered benign, 28 questionably malignant, and 15 definitely malignant with metastases to the liver.

The tumors may be single but two or more have been found in approximately 10 per cent of the reported cases. They are usually in the body and tail of the pancreas but may be in the head of the gland. They are dark red or purplish in color and are larger than the surrounding tissues. Their size varies, but it averages between 1 and 3 cm. in diameter. The benign tumors are encapsulated. They may show signs of degeneration, but in some cases they are definitely calcified. Microscopic sections of the cells are typical of islet cells.

The symptoms of islet-cell tumors may be hunger, faintness, perspiration, and vertigo or in addition, there may be signs related to the nervous system. Wilder has classified the nervous symptoms into three groups: (1) disturbances of the sympathetic nervous system with diarrhoea, nausea, pallor and sweating; (2) disturbances of the central nervous system such as convulsions with tonic and clonic contractions of the extremities and (3) psychic disturbances with anorexia, manic-depressive mental confusion and coma.

These attacks occur most frequently during periods of fasting or overfatigue at which times the blood-sugar levels are lowest. There is frequently a rapid response to the ingestion of glucose either by mouth or parenterally. Whipple has presented a triad for differentiation of islet-cell tumors: (1) attacks of insulin shock coming on during fasting or overfatigue; (2) blood-sugar findings of 50 mgm. per cent or less; and (3) prompt relief from the ingestion of glucose. When this triad is present the possibility of islet-cell tumor due to oversupply of insulin must be seriously considered. The differential diagnosis of hypoglycemia is a difficult diagnostic problem. The influence of other glands such as the thyroid, pituitary, adrenals and liver on the carbohydrate metabolism must be considered.

Surgery is indicated in the severely ill patients who have not responded adequately to palliative measures. The transverse or inverted-T incision is par-

ticularly suited to the operation on the pancreas. The gland may be approached through the gastrohepatic or gastrocolic omentum. If most of the greater curvature of the stomach is freed and reflected upward practically the entire anterior surface of the pancreas can be visualized. Islet tumors may be quite obvious or not visible at all. Removal of the obvious adenoma usually is followed by complete relief of the symptoms. However these masses may be multiple and additional tumors should be removed when present. When no tumor can be found the procedure is open to debate. The surgeon may postpone further surgery until the tumor is sufficiently developed to permit its location and removal, or an adequate portion of the pancreas may be resected with the idea of reducing the secretion of insulin, which treatment is similar to that of hyperthyroidism. This is done with the hope that the removed segment of gland may bear the offending tumor.

SAMUEL J. FOOTE, JR., M.D.

Cole, W. H. and Reynolds, J. T.: Resection of the Duodenum and Head of the Pancreas for Primary Carcinoma of the Head of the Pancreas and Ampulla of Vater. *Surgery* 1945 18 133.

After describing the various operations for primary carcinoma of the head of the pancreas reported in the literature by Whipple (1941), Hunt (1941), Orr (1942), Brunschwig (1943), and Child (1944), the authors submit their procedure which they now have done on 5 patients.

A long midline or modified transverse incision is made in the upper abdomen in order to determine whether or not the tumor can be dissected free from the superior mesenteric and portal veins. The common duct is next divided as far distally as possible. The gastroduodenal and inferior pancreaticoduodenal arteries are then ligated. The pylorus and distal duodenum at the ligament of Treitz are then divided. Then a long loop of jejunum is brought up for an end-to-side gastrojejunostomy. Into this long loop of jejunum the common duct is transplanted as much distance as possible being left between the site of transplantation and the gastrojejunostomy in order to minimize contamination or exposure to the food stream. The cut end of the pancreas was not transplanted into the intestine in this series of patients because to date very little ill effect has been

Fig. 1. Technique of the one stage resection of duodenum and head of the pancreas adopted after trial with several different types. Note that the common duct is transplanted proximal to the gastrojejunostomy so that the food stream will not pass over it but will pass downward (assisted by gravity) instead of upward and over the transplanted duct as in some operations recommended.

Insert shows an alternate procedure of transplanting the cut end of the pancreas into the jejunum. The proximal loop of jejunum is left long to make room for transplantation of the common duct and if desired, also the stump of the pancreas; however it need not be so long if transplantation of the stump of the pancreas into the jejunum is not done or contemplated.

observed by the various authors reporting on this subject following complete closure of the pancreatic stump.

It is advisable to insert a drain down to the stump of the pancreas because a pancreatic fistula develops so commonly in spite of efforts to ligate the pancreatic duct and close the stump of the pancreas with nonabsorbable sutures.

One of the first 5 patients operated upon died but as yet insufficient time has elapsed since surgery to determine the prospects of cure.

SAMUEL J. FOOTE, JR., M.D.

Danforth W. G. Vaginal Hysterectomy in the Management of Descensus Uteri. *Am J Obst* 1945 50 376

In 160 of a little more than 600 vaginal hysterectomies, the operation was done for descensus of greater or less degree.

In 1 case death occurred. The patient was a woman in whom the protrusion was about 5 or 6 cm. She came through the operation well but got out of bed the first night and was controlled with some difficulty. She developed pelvic inflammation and shortly thereafter pneumonia. The latter was the determining cause of death.

Vaginal surgery requires a definite knowledge of the anatomy of the region in which the procedure is carried out. It also demands a familiarity with the technique of the operations which are done in this field. The specialist in pelvic surgery should be familiar with both the anatomy and technique for the results of operations for descensus done from below are so much better than those following abdominal procedures that the latter should give way entirely. The safety of the operation done from below is greater and this fact should weigh heavily in the choice of procedure. It is the author's opinion that vaginal hysterectomy rather than the procedures of the Manchester type particularly in cases of extreme descensus, is the operation of choice. In cases in which the descensus is of moderate degree either will serve. As in many patients the uterus has passed its usefulness and especially inasmuch as the cervix is often unhealthy removal of the uterus has a much larger field of usefulness than the alternate procedure.

Abartanek, A. R., and Leatham, J. H.: Studies in Amenorrhoea, Oligomenorrhoea and Anovulomenorrhoea. The Effect of Equine Gonadotropin upon the Establishment of Cyclic Menstruation and Ovulation. *Am J Obst* 1945 50 562.

Twenty two patients with clinically hypofunctional ovarian activity were studied. These included 3 with primary amenorrhoea 11 with secondary

amenorrhoea 8 with oligomenorrhoea and 1 with cyclic anovulomenorrhoea. Adjuvant therapy with equine gonadotropin was instituted in these cases the amounts varying from 400 to 4,000 units.

This hormone failed to establish menstruation in 3 cases of primary amenorrhoea.

Of the 11 cases of secondary amenorrhoea ovulation was apparently stimulated in 2 although the result in 1 was open to serious question. Only 1 patient continued to have regular menses.

In the 7 cases of oligomenorrhoea the equine gonadotropin apparently restored cyclic menses in 1 case but failed to stimulate an ovulatory response in any.

In the 1 case of regular anovulomenorrhoea equine gonadotropin was ineffectual.

Nine of these 22 patients were later salvaged with an adequate diet and usually thyroid extract.

Clinically equine gonadotropin proved to be a rather ineffectual stimulant to the abnormally functioning or hypofunctioning human ovary as far as the restoration of normal cyclic metabolism and the reappearance of regular menstrual rhythm was concerned.

Equine gonadotropin produced similarly poor results in stimulating an ovulatory response in patients with clinically hypofunctioning or abnormally functioning ovaries.

The principle of heterogeneous substitutive therapy with equine gonadotropin may yield far greater harm than any temporary good. The possible harmful results of therapy with equine gonadotropin are (a) a gonadotoxic effect on the ovary as evidenced by abnormal stimulation or marked delay in the appearance of the next menses (b) the development of antagonistic (antigonadotropic?) substances with neutralization of subsequent injections of equine gonadotropin, (c) the development of allergic manifestations which may be severe in spite of negative skin tests and (d) the sensitization of the patient to other as yet unknown components of horse serum.

The principle of physiological stimulative therapy by means of a nutritionally balanced diet and desiccated thyroid extract is far more rational and far more efficacious both on theoretical considerations and with regard to the clinical results obtained.

PREGNANCY AND ITS COMPLICATIONS

Berman W.: Congenital Absence of the Sacrum and Coccyx Complicating Pregnancy. *Am J Obst* 1945 5 447

Röntgenograms of the pelvis of a 20 year old primipara at term showed a single fetus with its back to the left and the small parts to the right. The head was above the pelvic inlet and ballotable on palpation above the brim of the pelvis. The head appeared to be full term in size. The pelvic inlet was asymmetrical. The vertebral column was straight and terminated at the junction of the last lumbar vertebra and the pelvic girdle. There were two marked depressions at the site of the posterior superior spines of the ilium. There was almost a complete absence of the interpleural fold, and the subcutaneous tissue and muscle formed a partially loose apron over what would normally be the sacrum.

The uterus responded to labor like any other normal uterus. Contractions were regular and of sufficient strength to require the use of some analgesia. The cervix dilated but there was no descent of the head.

After 24 hours of active labor without progress, a low classic cesarean section was done. The infant died shortly after delivery. Autopsy revealed that it had a congenital heart lesion and complete atelectasis of all lobes of the lungs. A roentgenogram failed to reveal any abnormality of the bony structure of the infant's pelvis.

Edw and L. Coakley, M D

Chealey L. C., and Williams, L. O.: Renal Glomerular and Tubular Function in Relation to the Hyperuricemia of Pre-Eclampsia and Eclampsia. *Am J Obst* 1945 59 367

Simultaneous measurements were made antepartum of the serum clearances of insulin, urea, and uric acid in 10 normally pregnant women near term, and in 10 women with pre-eclampsia and eclampsia. In all but 3 of the normal women, the tests were repeated postpartum.

In pre-eclampsia and eclampsia the uric acid clearance is reduced. In this series, the diminution averaged 50 per cent. On the average, the reduction in uric acid clearance depends equally upon 2 factors, viz., (1) a decrease in the rate of glomerular filtration, and (2) an increase in the tubular reabsorption of uric acid from the glomerular filtrate. The increased tubular reabsorption of uric acid is the more general of the 2 factors.

Published data of other workers have been interpreted to support these conclusions. The diminution in uric acid clearance appears adequate to explain the hyperuricemia of pre-eclampsia and eclampsia.

Edward L. Coakley, M D

Leonard, M. F.: Hemolytic Disease of the Newborn (Erythroblastosis Fetalis). *J Pediatr* S. Lusk, 1945 7 249.

Fifty five cases of hemolytic disease of the newborn treated at the New York Hospital, New York, in the 6 years from 1938 to 1944, are summarized. The clinical picture was extremely varied, jaundice, anemia, the degree of erythroblastosis, and hemorrhagic manifestations varied independently. A high incidence (44 per cent) of bonepneumonia was noted. The effects of transfusion with Rh-positive Rh-negative blood and bank blood were typed for the Rh factor were compared. The immediate results following the transfusions in raising the hemoglobin and improving the clinical condition were equally good but Rh-negative blood transfusions resulted in a better sustained rise in hemoglobin, fewer reactions and lower mortality. Nine infants died, a mortality of 34 per cent. One of the chief causes of death was hemorrhage.

Jaundice out of proportion to or in the absence of anemia was attributed to impaired liver function. This theory was supported by the fact that low prothrombin levels responded poorly to vitamin K administration, by the pathological findings of fatty degeneration and necrosis of the liver and the evidence obtained from the literature.

The necessity for immediate transfusion in the presence of normal blood levels was questioned, and reasons were given for delaying transfusion until anemia impends. Plasma infusions were preferred in this type of patient.

The prominence of hemorrhagic tendencies in patients with hemolytic disease of the newborn was emphasized and its relation to low prothrombin levels demonstrated.

Administration of vitamin K to donors of Rh-negative blood was suggested as a means of raising the prothrombin levels of affected infants.

CHARLES B. ROSS, M D

Miller H. C.: The Effect of the Fetal and the Birth Weight of the Newborn Infant. *England J Med* 1945 33 376.

One of the outstanding characteristics of pregnancies in diabetic mothers is the high fetal and neonatal mortality rate. In addition, in some infants born to diabetic mothers there are striking somatic and visceral changes, including an increase in birth weight, cardiomegaly, hyperplasia of the islets of Langerhans, excessive extramedullary erythropoiesis, hyperplasia of the adrenal gland, and an increase in the eosinophil elements of the anterior pituitary body. Similar observations have been made on infants born to mothers who were

diabetic at the time of delivery but in later months or years developed signs and symptoms of diabetes. Since all the mothers who have been studied thus far became diabetic during the childbearing period, that is, under 40 years of age, it was considered desirable to extend the observations to infants born to mothers whose diabetes appeared after they had passed the fourth decade.

The fetal and neonatal mortality rates and the average birth weight are increased among infants born to mothers who subsequently manifest diabetes mellitus, even though the latter do not develop the disease until after forty years of age. The fetal and neonatal mortality rates increase as the onset of maternal diabetes is approached. Maternal obesity is not a factor in the increased average birth weight of infants born to prediabetic mothers who become diabetic after the age of 40. CHARLES BARON M.D.

Comfort, A.: Congenital Syphilis in an Infant Treated with Penicillin. *Lancet* Lond. 1945 249 431

A syphilitic mother was given 8 injections each of napharside 0.04 gm. and bismuth 0.2 gm. and a month later gave birth to a child weighing 6 lb. 3 oz. at birth. At one month of age the female infant was found to have strongly positive Wassermann and Kahn reactions, and two weeks later developed a rash, nasal discharge and dyspnea. Her weight at this time was 7 lb. 14 oz. Her frontal bosses were prominent, her scalp was covered with thick black hair and the upper ends of the tibiae were tender and enlarged. The body was covered with a scaly polymorphic maculopapular rash and there was a copious mucopurulent bloodstained nasal discharge. The respiratory rate was 36 and moist sounds were heard in all areas of the chest. The temperature now rose to 106.5°F. and the respiratory rate to 70, an area of impaired resonance with tubular breathing developed on the right side and extended up the spine.

The child was started on sulfapyridine (1.75 gm.) in 4 hour doses, but on the second day intramuscular injections of 38,000 units of penicillin were started and stopped after 412,000 units had been given. Thereupon the temperature rose to 108°F. but it fell soon afterward to 102°F. The general condition of the patient remained about the same, the pertinent blood findings at this time being polymorphs 30 per cent and lymphocytes 50.5 per cent. Four hour injections of penicillin 9,500 units were started again and in 24 hours the temperature had fallen to normal, the nasal discharge had ceased and the pulmonary signs had begun to clear. However, an additional 95,000 units were given before the drug was stopped. Immediately the temperature rose again and there was a slight return of the nasal discharge. The epiphyses were larger and very tender. Injections of ung. hydrarg. nit. fort. to the abdominal wall was begun and 4 injections of 0.5 ccm. of acetylarsan were given every third day. After this the respiratory rate was still high but

pulmonary signs were almost absent. The temperature range was lower from 100 to 102°F.

Immediately the 4 hour injections of penicillin in 9,500 units were resumed. Once more the fall in temperature to normal was immediate and after a further 95,000 units were given it remained down.

Finally 4 days later 100,000 units of penicillin were given over a period of 3 days whereafter all medication was stopped and a week later the Wassermann and Kahn reactions were negative and the epiphysitis had subsided. Thus before the reversal of the Wassermann reaction there were administered 702,000 units of penicillin, and 3 c.c. of acetylarsan, also some mercury and potassium iodide. Since then the child has remained practically well and the Wassermann reaction has remained negative. A convergent squint persists but vision appears to be present and there is no choroiditis.

From this experience the author concludes that in these acute cases of congenital syphilis the combined therapy as given in detail should remain the method of choice. JOHN W. BRENNAN M.D.

MISCELLANEOUS

Miller V. F.: Tubal Patency Tests. *J. Am. M. Ass.* 1945 130 243

Uterotubal insufflation and uteroosalpingography are widely accepted and well established procedures for the determination of tubal patency or its absence, and the latter is discussed with regard to sterility in the female. This survey of hundreds of tubal insufflations and 400 cases of uteroosalpingography over a 24 year period shows the value of these procedures and has led to significant conclusions.

Genital infection, either salpingitis or cervicitis is the chief contraindication to the performance of either of the mentioned tubal patency tests like was pregnancy constitutional disease and pelvic neoplasms also contraindicate these tests. Thorough knowledge of the menstrual history and a pelvic examination immediately prior to the test are essential. The week following menstruation is the most satisfactory time for the performance of either test.

The use of gas insufflation and the intrauterine introduction of radiopaque substances are supplementary tests both necessary for a complete evaluation of tubal patency. The former procedure is used initially and the latter is generally reserved for those cases in which patency is not found following insufflation. In the simple procedure of introducing air or carbon dioxide (preferred) into the uterine cavity pressure observations are essential. A rise in pressure (under a constant slow flow of no more than 300 c.c.) to 120 mm. and a falling off to from 30 to 60 mm. is encountered with normally patent tubes. A progressive and persistent rise in pressure is reasonable evidence of nonpatency. Hystographic recordings of manometric data are important. In substantiating patency in both tubes or localizing it

In one the symptoms, first of lower quadrant pain and then of shoulder pain should be correlated with manometric readings and with auscultation over the right and left lower quadrants to ascertain if air is escaping from the tubes. The importance of repeated testing on successive occasions is stressed.

Röntgen visualization of the tubes is essential when atresia or complete tubal closure is revealed by insufflation, and permits more accurate localization of the obstruction, particularly when salpingostomy is contemplated. From 6 to 10 c.c. of a warm opaque medium such as lipiodol are used, and observations are made under fluoroscopy of the escape of the oil from the ostia or its retention in the tubes. Immediate 24 hour, and 48 hour roentgenograms are essential in each instance as a permanent record and often disclose the late escape of oil or the presence of oil in the peritoneal cavity to refute an earlier impression of non-patency. The therapeutic effect of oil in opening closed tubes has been observed, especially when the procedure is repeated. Although an ideal oil, which is nonirritating and affords a good visual contrast on the x ray plate at the same time has not been found the incidence of morbidity attendant on this procedure appears to be slight. On the basis of available data insufflation results in morbidity in less than 1 per 1000 cases; gas embolism is the chief pathological cause in the rare case. The percentage of morbidity following the use of oil is slightly higher, oil embolism having been reported in some cases during the earlier years of the development of the tests.

Both tests when used in conjunction with one another and when properly performed are safe and highly informative for the diagnosis of tubal patency.

PATRICIA B. CRANE, M.D.

Rinehart, R. E.: Serum Protein in Normal and Toxemic Pregnancy. *Am. J. Obst.*, 1945, 50: 41.

Two hundred and fifty-one determinations of the serum proteins of 79 normal pregnant women and 50 on 5 pre-eclamptic women were made.

The average value for serum globulin remains almost constant throughout normal and toxemic pregnancies. During the normal pregnancy the average value for the total protein tends to fall from the nonpregnant level to a minimum during the eighth and ninth month and to rise rapidly to normal after delivery. At its lowest point this represents a decrease of 7.1 per cent from the nonpregnant average. This decrease in the concentration of total protein is confined primarily to the albumin fraction. The albumin decreased from a nonpregnant average value of 4.0 to 3.0 gm. per 100 c.c., a fall of 4 per cent. The average value for total protein as pre-eclampsia was 14 per cent below that of normal women in the same stage of pregnancy. This decrease in total protein is confined to the albumin fraction. It was 13 per cent lower than the lowest average value obtained at any time during normal pregnancy and 33 per cent lower than the average for normal nonpregnant women.

The probable dependency of these changes on known alterations of the function of the liver during pregnancy has been considered. A total of 15 determinations of the serum protein in simultaneous drawn maternal blood and blood of the cord was made. The albumin content of maternal serum and serum of the cord is nearly identical; a slight difference is noted in the globulin fraction.

Vaux, N. W., and Rakoff, A. E.: Estrogen-Progestins; A New Approach in the Treatment of Habitual Abortion. *Am. J. Obst.* 1945, 50: 33.

A study was made of a group of 24 patients with habitual abortion who were treated with estrogen and progesterone. These patients had gone through a total of 80 previous pregnancies from which there had resulted only 7 living babies (9%). There had been 53 abortions, 13 miscarriages, 2 stillbirths, and 1 premature live birth in which the infant did not survive. Fifty-four per cent of the patients had no difficulty in becoming pregnant, 8 per cent were of diminished fertility and 38 per cent were of poor fertility. In none of these patients were there any pelvic abnormalities or systemic diseases which would influence abortion. In only 1 patient was the basal metabolic rate diminished. Two patients had Rh incompatibilities (Rh-negative wife and Rh-positive husband). One of these delivered a normal living baby and the others aborted in neither case did Rh antibodies develop.

Information about the endometrium obtained by biopsy or curettage was available in 11 cases before the present pregnancy. Good secretory function was noted in 7 cases; impaired secretory function in 2, and an interval endometrium in 2.

Urine hormone assays were made in 15 cases prior to the onset of pregnancy. Urine gonadotrophic assays made at the midcycle were normal in 37 per cent. Urine estrogen assays made at the midcycle and during the third week of the cycle were diminished in 67 per cent, while low or absent pregnandiol values were obtained in 53 per cent. Since these studies were made in only one cycle, their significance is limited.

Hormone assays consisting of determinations of the urine pregnandiol, serum estrogens, and serum gonadotropins were made early in pregnancy in 19 cases. In almost all of the cases one or more additional assays were made and in 3 cases monthly assays were done.

On the initial assay 95 per cent of the cases showed normal serum gonadotropins. Seventy-nine per cent had diminished serum estrogens and 83 per cent had diminished pregnandiol titers. In 13 of the 19 cases studied, both the estrogens and pregnandiol were diminished. These findings indicate a deficiency of the corpus luteum during the early weeks of gestation and an inadequacy of the placenta to take over its functions.

Many of the patients had been unsuccessfully treated in previous pregnancies with progesterone, thyroid, and vitamin E.

During the present pregnancy all patients were treated by the injection of progesterone (10 mgm) and alpha-estradiol benzoate (10,000 rat units) given together two or three times weekly. This treatment was generally continued to the period of viability or later.

There was fetal salvage of 16 babies, or 67 per cent. There were 15 full term live births (with 1 neonatal death due to congenital abnormalities) 3 premature live infants (2 survived) 2 miscarriages and 4 abortions.

EDWARD L. CORNELL, M.D.

Nicodemus, R. E., Ritmiller, L. F., and Ladden, L. J.: Continuous Caudal Analgesia in Obstetrics on Trial. *Am J Obst* 1945 50 312

Of 500 deliveries with caudal analgesia 469 of the patients had complete relief of pain and 16 had partial relief. 15 patients were unrelieved. The authors state that caudal analgesia has given a higher percentage of complete relief to the mother than any other method or any combination of methods that they have employed. They believe that no other anesthetic is required and that it is not necessary to call an anesthetist to control the patient for the final delivery and repair.

In the authors' experience, the patients were nearly always ready to eat a little food and drink fluids immediately after delivery. In fact, many of them were able to do so during the course of their labor all of which aided greatly in the maintenance of normal blood chemistry and consequently fluid and nutritional balance.

The analysis shows that in patients in whom caudal analgesia was used the labors were longer and uterine contractions were of less intensity and the

expulsive force of the abdominal musculature was lost. Spontaneous rotation occurred less often in occipitoposterior positions and operative deliveries were increased. Breech deliveries were easier and safer. There was a lower incidence of stillbirths, a lower maternal morbidity, diminished blood loss with delivery, less permanent damage to the birth canal, and the patients were pleasant happy and co-operative.

EDWARD L. CORNELL, M.D.

Hanley B. J. and Malone G. M.: Caudal Analgesia in Obstetrics with Special Reference to Repeated Single Blocks. *Am J Obst* 1945 50 306

The authors present the results obtained in a series of 1,935 patients with caudal block. A technique for complete analgesia and delivery under repeated single caudal injections with $\frac{1}{4}$ per cent tetracaine is described.

Single caudal block technique has a definite place in the practice of obstetrics. Its use is varied. It can be used as a single block for delivery, or it can be repeated throughout labor for analgesia and delivery. The results with caudal anesthesia and obstetric surgery are very encouraging. Single caudal block, when administered by an experienced individual under proper conditions, can be as safe as other forms of analgesia or more so.

Caudal block administered correctly will give as good results as any other form of analgesia. The use of interrupted single caudal blocks for analgesia and delivery gives promise of effectiveness and safety for mother and child. Caudal anesthesia in obstetrics should be limited to well equipped institutions which have a full time resident or a teaching staff.

EDWARD L. CORNELL, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Macgrath, B. G., Harvard, R. E., and Parsons, D. S.: Renal Syndrome of Wide Distribution Induced Possibly by Renal Anoxia. *Lancet*, Lond. 945 249-293

The authors discuss the nature and distribution of a type of renal failure seen in a great variety of acute illnesses. The syndrome is a condition of impaired renal function developing usually in an acute illness and often associated with a transient peripheral circulatory failure. The onset of oliguria or anuria is commonly the first sign. In patients who survive there is also a postanuric period of impaired renal function, with nitrogen retention and often a copious unconcentrated urine. The postanuric period may last for several weeks, but eventually there is complete and permanent recovery. The reversible nature of the renal failure is the chief feature that distinguishes this syndrome from the other forms of nephritis.

In patients who die the kidneys have a characteristic appearance postmortem. They are usually enlarged, with a swollen, pale cortex and often an engorged medulla. The epithelium of the convoluted tubules is degenerated, necrosed, or desquamated. The damage may be concentrated chiefly in the ascending loop of Henle and in the distal convoluted tubules. The lumina of the tubules are usually filled with debris and with desquamated cells either in tact or fragments. The debris is often stained deeply by the pigments which may be present in the urine at the time the lesions develop. It is a constant observation that the glomeruli and their capsules appear nearly if not quite, normal. The vessels of the medulla on the other hand, are usually engorged and often there are apparent hemorrhages into the lumina of the tubules.

The main features have been noted in widely differing conditions. In blackwater fever incompatible blood transfusion, and in icterus neonatorum there is extensive intravascular hemolysis but in recent years the syndrome has been frequently observed in crush syndrome, in which hemolysis is lacking. In the above mentioned conditions the syndrome is always associated with the presence of pigment in the urine, and it has been thought that the pigment, if not the immediate cause of the anuria is the cause of the damage to the renal tubules. However experiments designed to establish this have been inconclusive. The syndrome develops in many conditions in which abnormal pigment is absent from the urine. In the alkalosis of gastric tetany that may arise during the treatment of peptic ulcers similar nitrogen retention occurs accompanied by similar characteristic changes in the kidney. There are also many other conditions in which the features of this syndrome have been re-

ported. The anuria, the impairment of renal function, and the characteristic microscopic appearance of the kidney have been described in cases of septic abortion, cholera, yellow fever, Weil's disease, diabetes, hepatorenal syndrome, pernicious anemia, and carbon monoxide poisoning.

Three different causes have been suggested. (1) mechanical blockage (this does not account for the many similar cases of anuria in which pigment is absent, and it has now been generally abandoned) (2) a "nephrotoxic" effect of some injurious substance carried to the kidney by the blood-stream. (3) renal anoxia, the main cause of renal damage being the temporary deprivation of oxygen.

The nephrotoxic theory demands that a wide variety of toxins many of them hypothetical or at least unidentified, shall all produce syndromes which are very similar in their clinical and pathological appearances. The situation is not unlike that existing in the study of rickets before the discovery of vitamins.

The authors express the opinion that the evidence at present available favors the hypothesis that renal anoxia plays a large part in producing this syndrome, in that it results in damage to the renal epithelium, and consequent impairment of renal concentrating power. The oliguria and anuria that occur in many instances are probably the direct result of the disturbances of renal blood-flow that follow peripheral circulatory failure. If this is correct, it has an important practical application, for the prevention of anuria in these conditions will then depend more upon the support given to the circulation than upon efforts to keep the urine alkaline. Blood transfusion is the most effective means of providing the depleted blood stream with fresh oxygen-carrying power in conditions in which "shock" is accompanied by anemias, as in traumatic hemorrhage and in blackwater fever. To be effective however it must be given early.

The authors suggest that 'renal anoxia' is a suitable name for the syndrome.

JOSEPH K. NARAI, M.D.

Goyanna, R., and Greene, L. F.: Pathological and Anomalous Conditions Associated with Duplication of the Renal Pelvis and Ureter. *J. Urol. Med.*, 1953, 54: 1

Complete duplication of the renal pelvis associated with complete or incomplete duplication of the ureter is a common anomaly which in itself has no clinical significance. At the Mayo Clinic it was found 25 times in 2,000 consecutive autopsies, an incidence of 1.25 per cent. It is sometimes contended that duplication makes the upper part of the urinary tract more liable to pathological conditions. If such is the case, and in view of its relative frequency duplication may assume clinical importance.

If some associated pathological or anomalous condition is present one of the segments may be non-functioning and therefore roentgenographically invisible, which would create diagnostic difficulties. In a 10 year period 131 patients at the Mayo Clinic presented 154 pathological or anomalous conditions associated with complete duplication of the pelvis and complete or incomplete duplication of the ureters. The so-called bifid pelvis although theoretically a type of duplication was not included for its frequency is so great that it may be considered more as a normal variation than as a true anomaly.

The most common pathological condition found associated with duplication was hydronephrosis or hydroureter or both. This was twice as common on the right as on the left side and nearly twice as common in the lower as in the upper segment.

The fact that the incidence of pyelonephritis, pyonephrosis and atrophic pyelonephritis also is higher in the lower segment than in the upper one may be considered a consequence of the faulty drainage of the hydronephrosis. In all cases of ectopic ureter and in all cases of ureterocele associated with duplication, the ureter from the upper pelvis was the one affected.

The diagnosis of duplication is usually made with out difficulty by means of an excretory urogram. However if one of the segments is nonfunctioning the excretory urogram may appear normal. The following roentgenographic signs are suggestive of duplication (a) elongated renal shadow (b) the presence of a region of kidney with no means of drainage, or (c) the shape of the visualized pelvis.

Excretory urography alone cannot be depended upon to distinguish between complete and incomplete duplication of the ureters, unless the entrance of both ureters into the bladder is clearly seen. Cystoscopy and retrograde pyelography although helpful, may fail when the supernumerary orifice is hidden or when there is incomplete duplication.

A history of congenital incontinence associated with normal micturition is strongly suggestive of duplication with an ectopic ureter.

JOSEPH K. NARAT, M.D.

Shearer, T. P., Wiper, T. B. and Miller, J. M.: Renal Caruncles; a New Method of Treatment. *J. Urol. Balt.* 1945 54: 12.

The majority of renal caruncles reported in the literature have been treated by nephrectomy. In many instances, the lesion is of such size that considerable functioning renal tissue is sacrificed. However to date, mortality statistics favor the more drastic procedure of nephrectomy instead of incision and drainage alone or incision and drainage combined with nephrectomy at a later period. These mortality figures hold although nephrectomy is often extremely difficult even when a small inflammatory lesion is present. The perinephric tissues in these instances are frozen and the kidney is closely adherent to the surrounding structures, which makes its removal very difficult.

An almost universal observation is that the renal caruncle is preceded by a cutaneous infection such as a paronychia, boil, or a carbuncle. The time intervening between the cutaneous infection and the onset of symptoms due to renal disease varied from a few days to many months.

The symptoms are usually nonspecific in nature and do not point directly to the urinary tract as the seat of the difficulty. Malaise at times progressing to prostration chills, and fever is present. Urinary symptoms are lacking. It is not surprising therefore that the average length of time between the onset of illness and the institution of surgical treatment has been 66 days.

The authors have had occasion to treat an individual with a renal caruncle successfully by incision and drainage, combined with the administration of penicillin via the systemic and local routes. The patient was a 20-year-old white male whose presenting symptom for 2 months was pain of moderate severity in the left lower chest and upper abdomen. The pain was associated with temperature of a septic type which at times was as high as 103 degrees. Upon inquiry the patient stated that 4 days before the onset of pain he had had several boils on his face and 2 carbuncles in the right cervical region.

Laboratory examinations gave no information. The patient presented a few moderately enlarged lymph nodes in the inguinal regions and the intercostal spaces. Special studies of blood smears did not reveal evidence of a blood dyscrasia.

A review of the excretory urograms made before submission of the patient to treatment demonstrated the calyceal compression mentioned before. Retrograde pyelograms revealed that the middle and lower calyces of the left kidney were smaller than normal and were pushed medially. There was no alteration of the psoas muscle shadows in these roentgenograms.

The preoperative diagnosis was renal caruncle. As penicillin was available for postoperative therapy incision and drainage was deemed the procedure of choice.

The usual lumbar incision for exposure of the left kidney was employed. This incision was satisfactory but exposure was technically difficult because of the great number of adhesions which bound the kidney to the surrounding structures. Some increase in exposure was obtained by subperiosteal resection of a segment of the twelfth rib. The kidney was freed to the hilar structures anteriorly and posteriorly and carefully palpated. An aspirating needle was passed into several suggestive areas and purulent material was finally obtained from a site deep in the substance of the kidney at the junction of the upper two-thirds and the lower one-third. Subsequent needle punctures delineated the cavity which was entered with a ureteral scalpel. Ten cubic centimeters of thick purulent material were released and a No. 16 F. catheter was sutured into the cavity. Bacteriological examination of this material estab-

lished the presence of a hemolytic staphylococcus aureus in pure culture. One Penrose drain was placed at the upper pole of the kidney and a second one at the lower pole. The wound was closed in layers.

Penicillin treatment was instituted and 200,000 units of the drug were administered intramuscularly every day. In addition the abscess cavity was lavaged twice daily with 5 c.c. of a solution of penicillin containing 550 units per cubic centimeter. The response to treatment was gratifying. A scanty serous discharge persisted for about 3 days. The operative wound healed nicely and the temperature gradually became normal. Improvement in the general condition was rapidly apparent. Retrograde pyelography 25 days after operation revealed complete restoration of the calyceal structures to normal.

JOHN A. LOFF, M.D.

Tahara, C., and Hara, E.: Massive Renal Fibro-lipoma. *J. Urol. Balt.*, 94:5 54, 57.

Two enormous fatty tumors of the kidney are herewith reported. It is interesting to note that these tumors had existed for a considerable period of time, that they caused, apparently, hypertension and loss of weight and that they were both associated with a unilateral chronic pyelonephritis. In both of these cases, nephrectomy has reduced the blood pressure to somewhere within normal limits. Both patients were markedly improved by the surgery and both cases must be considered as benign from the pathological reports, but with definite malignant characteristics.

JOHN A. LOFF, M.D.

Goldstein, A. E., and Klotz, H.: Ligation of a Supernumerary Ureter. A Clinical and Experimental Study. *Am. J. Surg.* 1943 70, 13.

Intentional ligation of a ureter without performing a nephrectomy is rarely ever done except in experimental work. Intentional ligation of a supernumerary ureter without performing a heminephrectomy is the subject of discussion in this article.

The clinical application of ligation of a supernumerary ureter was used by the authors in 4 instances on 3 private patients, 1 patient having the operation performed bilaterally because of pain in bilateral supernumerary fused kidneys. The operation in all of the cases was performed because of pain either in the lumbar or abdominal region. In 3 cases the discomfort or pain was on the left side, whereas in 1 case it was bilateral. The pain had been present between 6 months and 7 years. It was intermittent at first but later became constant in all of the cases, and, although not sharp, was very acute in 2 cases, simulating either a kidney colic or Dietl's crisis. Activity seemed to increase the pain. None of the patients showed any evidence of infection either by the presence of pus or organisms. All were females under 40 years of age, 1 having borne children, whereas 2 had not. Two of the 3 were married.

Functional studies revealed a good output in the opposite kidney as well as a good excretion in the

lower normal segment. The function of the supernumerary or upper segment was found to be fair. The capacities of the pelvis of the upper segment were less than those of the lower ones, ranging between 3 and 5 c.c.

The pyelographic studies were made both by the intravenous and the retrograde method, and it was observed in all of the cases that the pelvis and the calyces of the upper segments were smaller than the pelvis and calyces of the lower ones. A reproduction of the pain was obtained in all the cases by inserting the supernumerary segment with water.

Numerous dilations, first of the supernumerary ureter and then of the other ureter on the same side, were performed in all of the cases. The number of dilations of the supernumerary ureter varied from 3 to 12. In 1 case the supernumerary ureter presented a real stricture at the orifice. In the other cases a No. 6 catheter met a slight obstruction which was easily overcome. None of the cases showed a dilatation of the supernumerary ureter.

The emptying time seemed to be normal, from 1 to 8 minutes, in all of the supernumerary segments.

Previous to the operation a catheter was placed in the supernumerary ureter. The ureter was exposed extraperitoneally through a Gibson incision. The midthird of the ureter was selected for the ligation. After the ureter had been freed for a short distance, 3 chromic catgut ties were placed around it, about 1/4 cm. apart. The ureter was cut so that 1 of the ties were left on the lower portion and 2 were left on the upper portion. A small portion was removed for examination. The upper portion of the ureter was observed for a few moments but no great perceptible dilatation occurred. No leakage of urine resulted from the operation so that the wound was closed without drainage.

All of the wounds closed by first intention. Particularly enough, while the patients had some pain after operation, which was the result of the operation, they all claimed it was of a different type. In all, the original type and location of pain seemed to have disappeared immediately after the operation.

Pyelograms of the remaining kidneys were made by the intravenous route. When the pyelograms were made it was observed in all cases that the dye did not come through the supernumerary segment but through the other 2 kidneys. In normal time, and that the appearance of the remaining pelvis was the same as in the original retrograde pyelograms.

The patients were discharged in from 12 to 22 days.

In this study it was observed that after a ureter is ligated and cut a hydronephrosis immediately starts. Although this never assumes a very large size, it is present. From a functional standpoint, the ureter ceases to secrete very shortly after ligation, which fact was also borne out by the experimental work, so that when an intravenous pyelogram was made, no dye was found in the kidney pelvis or calyces.

The pain appeared to subside almost immediately after the ligation although there was some side

GENITOURINARY SURGERY

the lumbar region for about 3 months in 2 of the cases which was described as a different type of pain. This was probably a postoperative ache that might be encountered following any operation. These cases have been followed from 6 to 7 years.

JOHN A. LOER, M.D.

BLADDER, URETHRA, AND PENIS

Jekely E. A. Bilharziasis of the Bladder (Vesical Schistosomiasis) *J Urol* Balt., 1945 54 39

The organisms producing bilharziasis of the bladder are the blood flukes, schistosoma hematobia discovered by Bilharz in 1851. They are small white worms belonging to the phylum platyhelminthes, and are sexually differentiated trematodes. Their home is, primarily in the vesical venous plexus of man. Here the male, a short, somewhat flat worm measuring from 10 to 15 mm in length and about 1 mm in breadth, mates with the female, which is more threadlike, and measures about 20 mm in length and $\frac{1}{4}$ mm in breadth. Each is equipped with two suckers, one at the proximal end and another on the ventral surface slightly caudal to the first. These suckers permit them to adhere to the venous walls, which avoids their haphazard dissemination by the flow of blood. The fertilized ova are deposited singly in file by the female along the courses of small submucous veins of the bladder. The eggs are deposited one directly behind another until no more space remains. This is then repeated from venule to venule, which not infrequently severely obstructs them. It is estimated that a pair of schistosoma hematobia may live as long as from 20 to 30 years, continuing this process throughout their lifetime. Eventually the eggs erode the wall of the venule and drop into the bladder cavity. Being free within the cavity of the bladder they are readily voided with the urine. To permit survival the ova must come in contact with fresh warm water immediately after voiding. From the ova, a miracidium larva emerges which, after a free life of about 6 hours enters a fresh water snail and seeks out the snail's liver where it passes through a sporocyst stage multiplying many times in number through a budding process, and then emerges from the snail as forked tailed larvae or cercariae. As cercariae, they swim about freely in the water and must find a human host within 48 hours in order to survive. With suckers, they attach themselves to the human skin, shake off their tails and burrow through. Entering the blood vessels, they eventually find their way to the liver where they grow to adult male and female. After attaining maturity they migrate to the vesical venous plexus where they mate and egg laying occurs, thereby completing the cycle.

The symptoms of bilharziasis of the bladder may be divided into four stages. In the first stage symptoms of skin irritation occur at the site of entry of the larva. These may be slight to severe pruritus and may completely escape the patient's attention.

During the second stage, generalized toxic symptoms may occur. The time interval is from 4 to 12 weeks after exposure. Again, these may be so slight as to not require medical aid. However headache, backache, and chills and fever with night sweats are the symptoms of which the author's patient complained upon his first hospitalization and they correspond to the migration of the parasites and the first egg laying by the females. At this time, the blood shows a leucocytosis and high eosinophil count. Not infrequently the abdomen is tender and the liver and spleen are palpable.

In the third stage, symptoms of bladder irritation become prominent. There is urinary frequency, dysuria, and hematuria. Ova are now found in the urine. This stage corresponds to the bladder condition observed by the author in his case at the cystoscopic examination a confluent papillarylike growth was found to cover the entire trigone. The areas surrounding the ureteral orifices were especially involved. Beyond the trigone on the posterior wall of the bladder three isolated areas typical of the trigonal involvement were present. This finding in the bladder could hardly be confused with a true papilloma because it was lacking in the fine villi and presented a deeper red to slight purplish color. The appearance was neither that of a papilloma nor of a bullous edema rather something midway between. Interspersed in the area involved were several discrete yellow to gray nodular masses.

The fourth stage corresponds to the symptoms and pathological changes encountered in its many varied forms from the time of the passing of the ova in the urine to the death of the patient unless treatment is instituted. During this stage, the bladder findings are typical of the changes encountered in long standing chronic bladder irritation. There is proliferation of the mucous membrane with subsequent necrosis ulceration and secondary infection. Secondary stones are common and phosphatic deposits frequently cover large areas of the inflamed bladder wall. Subsequent fibrosis and scar tissue occur. The bladder capacity is diminished, at times to the point of complete incontinence. With bladder fibrosis and contracture in which the lower ureter takes part ureteral obstruction progresses. Hydronephrosis, renal infection, anemia, and sepsis follow. The secondary pyogenic infection may extend through the bladder wall and urethra, producing perivesical and perineal abscesses with suprapubic and rectal fistulas. Elephantiasis of the genitalia due to interference with lymphatic drainage has been reported. A true papilloma stage has been reported. Malignant changes may occur producing the characteristic findings and symptoms, and to eventual death from papillary carcinoma of the bladder. In severe infestations, the prostate seminal vesicles are also frequently involved. Results in infections, abscesses and fibrosis of the organs. Ova have been found in the semen of cases. In women the disease is less frequent, vaginitis, cervicitis, ulcers, papillomas of the

and carcinoma of the bladder have also been reported.

Fairley's complement fixation test is said to give a group positive reaction during the latter part of the incubation period. At the present time, the diagnosis of bilharziasis of the bladder must await the symptoms and findings of bladder disease. Ova containing the characteristic terminal spine in the voided urine, the cystoscopic picture and biopsy of the affected bladder wall clinch the diagnosis.

The author's patient was treated with fusidin, a trivalent sodium antimony compound. It is administered intramuscularly in the dosage of 50 c.c. on alternate days after the first two injections of 15 and 30 c.c. given on successive days. A total of 400 c.c. is given over a period of 16 days.

The necessity of early diagnosis as well as early, proper and adequate therapy is absolutely essential if a complete cure is to be attained. Prevention of human infestation is, of course, the first and most important problem. In countries such as Egypt swamps and lakes have been drained the courses of streams changed vegetation laboriously removed from lakes and streams to starve the snail, the intermediate host and wholesale poisoning of the snails has been done, but without any noteworthy success. The fundamental approach lies in the education of the natives and in winning their co-operation in preventing themselves early for treatment.

JOSEPH K. NARAT, M.D.

Oppenheimer G. D.: Late Invasion of the Bladder and Prostate by Carcinomas of the Rectum or Sigmoid. *J. Urol.* Balt., 94:5 54 1935

Fifteen cases of late invasion of the bladder and/or prostate and seminal vesicles following abdominoperineal resection for cancer of the rectum or for obstruction due to sigmoid cancer are reported. Direct involvement of the lower urinary tract by cancer of the lower bowel occurs frequently in 50 autopsies of patients with cancer of the rectum, 20 per cent of whom had a rectal resection the bladder was found to be invaded 31 times. Bladder, prostate and seminal vesicle involvement in the male, and bladder and uterine involvement in the female, apparently takes place by direct extension. Twenty two of the 50 cases (44%) showed compression of one or both ureters. Metastases to the ureters or kidneys were uncommon. At least 10 per cent of the patients who survive abdominoperineal resection have late involvement of the bladder, prostate, or seminal vesicles.

Palliative urological or surgical measures and radiotherapy should often be attempted even after lower urinary tract involvement because life may be prolonged this was shown by 2 reported cases. In one an obstructive sigmoidal resection was performed for infiltrating adenocarcinoma after preliminary cecostomy 4 years later cystoscopy was performed for hematuria, and a 1½ cm. postero-superior bladder tumor was fulgurated two years later another tumor reported as adenocarcinoma

was fulgurated. The second patient had a transurethral resection of recurrent adenocarcinoma involving the bladder neck and prostate, 7 years after abdominoperineal resection and radiotherapy. Histologically the transurethrally resected tissue was definitely secondary to direct extension from the residual rectal growth.

The results obtained justify attempts to undertake radical surgery even though the local lesion is fixed to the surrounding structures, and also justify late palliative urological therapeutic efforts.

DAVID ROSENBERG, M.D.

GENITAL ORGANS

Greene, L. F., and Thompson, G. J.: Transurethral Prostatic Resection in Patients with Advanced Renal Insufficiency. *J. Urol.* Balt. 94:5 54 1935

Transurethral prostatic resection can be performed safely in the presence of advanced renal insufficiency and suprapubic cystostomy preliminary to prostatectomy is no longer considered necessary. By means of transurethral prostatic resection free urinary drainage through the natural urethral channel can be quickly and safely restored.

Fifty four case reports are presented, in which transurethral prostatic resection performed in the presence of severe renal insufficiency is described. The blood urea was well above 100 mgm. per 100 c.c. in every case and resection was performed a bench blood urea, although reduced, still remained 100 mgm. or more in the large majority of patients the urea was higher than 150 mgm. per 100 c.c. of blood, and in almost half it was more than 200 mgm. per 100 c.c. The youngest patient was 49, and the oldest 79. Fourteen patients had severe hypertension, and 10 had cardiac disease. Profound acidosis was present in every case. In practically every case the urine specific gravity was fixed and less than 1.015.

Preoperative treatment consisted of urethral catheter drainage, the intravenous administration of fluids so that the daily urinary output was between 5,000 and 3,000 c.c. the intravenous administration of sodium lactate or bicarbonate for acidosis, and blood transfusions for anemia. Treatment was continued until the blood urea and the carbon dioxide combining power were stabilized, which was the optimal time for operation. In more than two-thirds of the cases the necessary preoperative preparation was completed within two weeks.

Prostatic resection was usually performed under spinal anesthesia, and occasionally under pentothal sodium. In more than half of the cases it was necessary to remove more than 30 gm. of prostatic tissue in order to relieve the obstruction completely. Frequently the prostate glands were small when they were most obstructive and this has led to failure in the diagnosis in a number of cases in which the patients' complaints were of nausea, vomiting and anorexia. Particular care should be taken to remove all of the obstructing tissue.

GENITOURINARY SURGERY

Of the 54 patients, 1 died of coronary occlusion 2 days postoperatively. More than half of the patients were able to leave the hospital within 2 weeks. The instillation of 1 750 solution of gentian violet into the bladder was the most effective method of stimulating the return of vesical tone. In some patients, when the blood urea had remained stabilized preoperatively in spite of further drainage and intravenous fluids, resection resulted in a fall of the urea concentration of the blood.

Follow up on 45 patients showed that 29 were alive and 16 were dead at the time of the report. Of the 29 alive, 2 in 2 years, 2 in 3 years, and 15 in less than 1 year. Of the 16 dead, 2 in 3 years, and 14 in less than 1 year. Of the patients who remained in from 5 to 8 years. Of the patients who lived at present, more than half have lived three or more years since resection. Although many patients had gastrointestinal symptoms prior to resection none of them has had a recurrence.

Transurethral prostatic resection can be performed on patients with advanced renal insufficiency with minimal risk, and the surgeon should not hesitate to perform resection in cases of this type. It has resulted in great economic advantage to these patients. Thus transurethral resection has provided surgical relief of patients suffering from prostatic obstruction and renal insufficiency.

DAVID ROSENBLUM, M.D.

W. H. Asepsis in Prostatectomy *Brit J Surg* 1945 33 41

In an effort to devise a technique of prostatectomy with an asepsis emulating that of other surgical procedures, the author has experimented with various possibilities in the cases of more than 600 patients during a period of about 6 years. The present study however is based on only the last 300 patients of the series after the experimental period had passed and the methods had become more or less fixed. In this technique, the author repudiates all use of the catheter or indeed of anything passed through the urethra. If it is necessary to relieve stress in acute retention he believes that the bladder should be punctured suprapubically with a spinal puncture needle. All manipulations are carried out suprapubically the bladder is decompressed at once and the full prostatectomy is then carried out in the normal way. After the prostate has been enucleated meticulous hemostasis is provided by means of a hemostat to which is attached the diathermy cable, deep bleeding being rendered accessible by the commonly advocated removal of the V-shaped, or semicircular, portion of the trigone by means of a "live" needle held in the jaws of the hemostat. Any blood clots are removed by suction and not with a swab. A couple of ounces of 5 per cent sodium citrate solution will prevent further clots in the prostatic bed and bladder.

A rubber tube is then passed from the bladder through the urethra in a retrograde fashion with the attached remnant of the prostatic urethra as a guide. To pass this tube the distal end is tied to a black French bougie with its bulbous proximal end

cut off. The rubber tubing and bougie are well covered with acriflavine-vaseline, which it is hoped will act as a pack around the tube within the urethra. The bladder should be securely and completely closed after which it is suctioned to evacuate citrate, air and any blood clot the last being rare. From 2 to 10 oz of sodium citrate solution are left in the bladder and a spigot is inserted. This spigot is removed about two hours after the operation and the tube is connected with further sterile tubing and let into a sterile Winchester bottle of sterile water.

It takes from one day to one week for the urine to become clear but if the clearance is delayed for more than 3 days infection must be suspected. Hematuria not requiring interference occurred in this series of cases in the author's opinion this indicates cystitis.

The operation is done under low spinal anesthesia and the patient is out of bed every day after the operation if only for a few minutes. Chemotherapy, which consists of not more than a half gram of sulfamethazone or sulfathiazole every 6 hours, is stopped on the fourth day but is renewed with the greatest intensity at the slightest sign of sepsis.

With this method (roughly outlined here for the purposes of this abstract) the author procured results which are characterized as startling. The more so as during the period of this series of operations only 335 cases of definite prostatic obstruction were seen. The surgeon refused to operate in only 6 instances in 5 patients the condition was sarcomatous. In the other patient the condition was sarcomatous. Twenty nine of the 335 patients refused operation or went elsewhere, and 300 were operated upon.

For the purpose of analyzing the mortality the material is divided into four groups. Group 1 consisted of patients in whom there was no marked systemic disease. In this group the residual urine at operation was 6 oz. or under indigo-carmin urine was passed through the urethra in less than 10 minutes and the urine was normal usually acid, and the blood urea 50 or under. This group included 189 patients with 4 deaths.

Group 2 included patients with mild systemic disease an indigo-carmin output in 15 minutes or less, a residual urine of under 15 oz. and a blood urea of 80 or under. The urine was often infected sometimes the pyuria was marked. In this group 31 prostatectomies were done, with 5 deaths.

Group 3 included patients with marked systemic disease usually cardiovascular. The residual urine ranged from 1 to 5 pints the blood urea commonly varied between 80 and 200. In this group were 31 operations with 5 deaths.

Group 4 was made up of those patients who had blood urea of over 200 and who showed evidence of cardiovascular failure, with edema, uræmic anemia or vomiting. This group (expressing an attempt to find the limit of aseptic prostatectomy) included only 6 patients, with 4 deaths.

Thus there was a total mortality for the 300 patients of 6.0 per cent. This mortality cannot of

course be compared with previous figures for this operation because of the lack of figures in other statistics with reference to the preoperative mortality with suprapubic drainage or with the indwelling catheter that is, septic prostatectomies. However a comparison can be had with the former results obtained by the author in that the present mortality is probably about one-fifth of what it was 6 years ago.

JOHN W. B. LEWIS, M.D.

Barnes J. L.: Teratoma of the Testis; Report of 65 Cases. *Am. J. Surg.* 945 54 257

Teratoma of the testis was observed in 65 patients during a 33 month period. These cases made up 7.86 per cent of all the malignancies admitted to the author's hospital. The average age of the patients was 28 years.

The cause of testicular tumors is unknown. It is thought that abnormal development, especially ectopic or undescended testes, may be a factor. This was present in 3 of the 65 cases. Trauma was mentioned in 21 instances, but apparently the trauma served only to direct attention to the tumor. Trauma as an etiological factor is still disputed.

Early diagnosis is of prime importance. Twenty-seven (41.5%) of the 65 patients were treated for other conditions before a malignancy was suspected. (The rapidity of the development of metastases in teratomas is unbelievable at times. The abstractor recently saw a patient who was treated for a hydrocele. The chest film was negative. In less than 1 month the patient developed a large liver which filled the epigastrium and the chest film revealed numerous metastatic depositions throughout both lung fields.) Forty-five of the patients (69%) had painless swelling. 24 (37.5%) complained of pain and 6 (9%) complained of a feeling of heaviness or dragging. Three-fourths of all the patients were treated within a year of the time the tumor was noted.

The history and course of the condition may be suggestive of testicular tumor. A smooth rapidly growing mass, inguinal adenopathy, neuralgia, tenderness to palpation, and nontransillumination to light are a few of the diagnostic findings. Teratomas must be differentiated from epididymitis, hydrocele, hematocele, gumma, and tuberculous and chronic orchitis. If there is doubt as to the diagnosis, a surgical exploration should be performed. Most of the tumors were found to be of the embryonal type, adenocarcinoma, or embryonal carcinoma.

Treatment consisted of a combination of surgery and irradiation. The surgery was radical orchiectomy and when possible, it was followed by irradiation on the third to fifth day. The cases were divided into those with no metastasis or with symptoms of less than 6 months and those with metastasis or with symptoms for longer than 6 months. In the first group the operative site, midabdomen, epigastrium, posterior sacrum, abdomen, and flanks were treated. In the second group in addition to the aforementioned fields, the lateral abdomen,

chest, and supraclavicular region were also treated. The following factors were used: 220 kv p., 15 ma., 50 cm. target skin distance from 0.5 to 1 mm. of copper plus 1 mm. of aluminum for filter, and from 200 to 250 r per each of two ports daily for a total dose of between 1,600 and 3,000 r per port.

A careful follow-up was made and after 33 months only 7 of the 65 patients who had been treated had died. The others were living and well.

MISCELLANEOUS

Forrythe W. E., Jr., and Karian, S. C.: Enuresis in Young Male Adults. *J. Urol.* Balt. 945 31

All cases of enuresis warrant complete study. A history is taken and specific urological questions are asked. The physical examination and laboratory investigation are routine. The patient is then placed under the joint observation of the urologist and the neuropsychiatrist. The former has excretory urograms made and performs cystoscopy and such other urological procedures as appear indicated. The patient is examined both neurologically and mentally. A cystometric study is then made and studied in detail. Emphasis should be placed on the importance of cystometry in the study of enuresis. By this means intravesical pressure changes which are produced by detrusor tone or activity in response to the introduction of known amounts of fluid are observed. Correlated with this is a sensory analysis. The authors prefer the use of a modification of the Munro water cystometer.

The following components are observed:

1. Sensation
2. First desire to void
3. Capacity. This is normally from 350 to 450 cc. and, as expected, varies with the reflex arc.
4. Intravesical pressure curve
5. Uninhibited contractions
6. Initiation of urination
7. Residual urine.

The following classification of the causes of enuresis therefore seem quite logical: (a) organic, congenital or neurological, and (b) functional.

The treatment of enuresis is based primarily upon making a correct diagnosis. It is quite obvious that attempted psychotherapy is time wasted when the true cause is organic. In cases in which local therapy is discovered, eradication of this process is usually followed by cessation of the symptoms. The good results which follow urethral dilatation, silver instillation, and vesical lavage may have been due in many instances to the inadvertent treatment of the local pathology.

The treatment of neurological cases remains very difficult. In addition to the old remedy of limitation of fluids, parasympathetic depression may aid in reducing the uninhibited contractions. In general, it has been found that these cases at best respond slowly to therapy.

GENITOURINARY SURCFKY

Free, A. H., Huffman L. F. Trattner H. R. and Brown H. B. Oral Penicillin in the Treatment of Gonorrhea. *J Lab Clin. M.*, 1945 30 738.

All of the patients in the authors series were diagnosed as having gonorrhea by means of positive cultures, clinical signs, symptoms, and history. The penicillin used was in the form of a dry powder contained in gelatin sleeve capsules. Each patient in the study received a total of 1,600,000 units of penicillin over a 2 day period. The dosage schedule required that 100,000 units be taken every 2 hours during the waking period. Two urethral cultures in the male patients and 2 urethral and 2 cervical cultures in the female patients were obtained during the 10 day period following treatment, and in most of the patients a third culture was obtained at a somewhat later time.

Altogether 14 patients with gonorrhea were treated by the technique described. In all instances only negative cultures were obtained following the treatment, and all of the clinical signs and symptoms of gonorrhea disappeared.

JOHN A. LOFF, M.D.

Cutting, W. C., Halpern R. M. Sultan E. H. Armstrong, C. D. and Collins, C. L.: Penicillin by Mouth for Gonorrhea. *J Am Med Ass* 1945 129 425

Extensive trials of the administration of penicillin by mouth, with various enteric coatings and adjuvants to protect the penicillin or promote its absorption, resulted in the following useful combinations: mixtures of penicillin with tri isopropanolamine, trisodium citrate, or sodium carbonate enclosed in a resin-cellulose plastic enteric coating.

When the dose of penicillin was 50,000 units, administered every 2 hours for 10 doses these superior combinations produced penicillin blood concentrations of from 0.02 to 0.05 unit per cubic centimeter.

Fifty three cases of acute gonorrhea were treated with several of the most promising combinations, with cures in 38 or 72 per cent.

Treatment of infections with highly susceptible bacteria by orally administered penicillin appears to be feasible.

JOHN A. LOFF, M.D.

Dyar R., Scholtz, J. R. and Hammond, E. C.: Penicillin Treatment of Previously Untreated Acute Gonorrhea. *Am J Syph.*, 1945 29 563

Four hundred and ninety-eight patients with previously untreated acute gonorrheal urethritis were treated with penicillin. Eighty three per cent of those treated with 50,000 or 75,000 Oxford units were considered cured on the basis of negative smears and/or cultures thereafter. Ninety-one per cent of those treated with 100,000 units of penicillin at one of those treated with the same dose. All patients considered cured on the first treatment were subsequently cured by retreatment with penicillin. The proportion cured did not vary significantly with the duration of symptoms prior to the institution of

treatment. There were no treatment reactions of significance.

Cases responding to penicillin therapy showed early clinical improvement and were generally bacteriologically negative 24 hours after treatment. The validity of the criteria of cure used was established by the re-examination from 6 to 12 weeks after the last treatment observation of 119 of the individuals originally considered cured on the basis of 21 days of post treatment observation. Among the 119 cases selected at random there was a positive smear or culture after rigorous tests of cure, in only one case.

JOHN A. LOFF, M.D.

Lydon F. L. Trichomonas Vaginalis Infection in the Male. *Brit Med J* 1945 2 384.

The frequency of trichomonas vaginalis infection in the female has for many years been recognized but the similar infection in the male has not received the attention it merits, since it is by no means an uncommon cause of urethritis. During the past few years the author has seen numerous cases of this nature, some of which he was fortunate enough to observe over many months, and the results of his investigations are put forward in the hope that with a higher index of suspicion when confronted with urethritis especially one showing a tendency to relapse and chronicity other workers will discover that many of the cases are due to infection with trichomonas vaginalis.

As for all chronic conditions especially when subject to remissions there are a multiplicity of cures. It is the author's opinion that, at this time there is no specific treatment for the condition although many methods have been advocated to bring about amelioration of the signs because the propensity to relapse is similar to that in the female even when no further exposure is possible. It is essential, therefore, to prolong surveillance over many months. Recently the administration of mepracrine hydrochloride, both in the usual dosage and by the intensive method now employed for malaria has been tried, but although the discharge decreased to a very slight amount and the active organism disappeared from the discharge the tell tale resisting cell could still be found on careful search. This drug may prove a failure too when subjected to the test of long surveillance.

JOHN E. KIRKPATRICK, M.D.

Lehr D.: Experimental and Clinical Studies with Sulfacetamide (p-Aminobenzenesulfonamide): Toxicity and Efficiency in Bacillary Infections of the Urinary Tract. *J Urol* Balt. 1945 54 87

Comparative studies of the acute and chronic toxicity of the sodium salts of sulfacetamide sulfadiazine and sulfanilamide have been carried out in albino rats by the intraperitoneal route of drug administration.

Figured on the basis of the medium lethal dose (LD50) sodium sulfacetamide possesses by far the

lowest acute toxicity being about five times less toxic than sodium sulfadiazine and more than seventeen times less toxic than sodium sulfanilamide. Based on mean values of the highest blood levels reached with fatal dosages of the three sulfonamides the relationship of the acute toxicity of sulfacetamide, sulfadiazine and sulfanilamide is as 1 to 3 to 10. (This relationship is expressed for equal weight amounts of the respective sodium salts.)

The chronic toxicity of sodium sulfacetamide is likewise lower by far than the toxicity of sodium sulfadiazine. At a daily dosage level of 0.6 gm. per kgm. body weight continued over a period of 9 weeks, sulfacetamide caused no significant pathology, anatomical lesions. The equimolar amount of sulfadiazine (0.7 gm per kgm.) however invariably produced severe organic damage particularly in the kidneys and in many instances also in the aorta.

The mechanism of the nephrotoxic action of the sulfonamides was discussed. The low renal toxicity of sulfacetamide was explained as being due to its high solubility (in water sulfacetamide is about 115 times as soluble as sulfadiazine) which apparently precluded the serious consequences of massive and long-lasting intratubular deposition of crystals which occurred from sulfadiazine.

The ready absorption and rapid renal elimination of sulfacetamide as well as its high solubility particularly in urine made it possible to obtain high urine concentrations in the presence of relatively low blood levels.

In *in vitro* antibacterial experiments it was found that sulfacetamide exerted a powerful effect against *Escherichia coli* communior even if very large inocula were used.

In comparative studies of sulfacetamide sulfathiazole and their succinyl derivatives using a streptococcus strain freshly isolated from a patient with infection of the urinary tract sulfathiazole proved significantly more effective than sulfacetamide in low concentrations (5 to 10 mgm. per cent) whereas in concentrations generally obtained at the bedside under routine treatment (50 to 110 mgm. per cent of the free drug) there was little difference in the antibacterial effect of the two compounds.

Conjugation with succinic acid at the para-amino group decreased the bacteriostatic activity of both compounds very markedly.

The results of these experiments suggest that from a pharmacological and toxicological standpoint, sulfacetamide deserves preference over other sulfonamides now in use for the treatment of infections of the urinary tract.

JOHN A. LOFF, M.D.

Keyser, L. D.: Studies in Urinary Calculosis. *J Urol Balt.*, 1945 54 94.

The author has tried to fit together some of the evidences of the origin of urinary calculi from the physicochemical, bacteriological and pathological standpoints as revealed by animal experimentation and the study of stone-forming kidneys. He presents the concept of a stone-forming pyelonephritis

which parallels in some degree that of other types of crystalline deposition in tissue.

Among the contributions of our generation to stone research, four are outstanding.

1 The demonstration of lithiasis in vitamin-starved animals.

2 The experimental production of stone in animals by excessive excretion of crystalloids such as oxamide, calcium oxalate and calcium carbonate, with later clinical confirmation of such a hyperexcretory mechanism in hyperparathyroid disease, in gout, and in certain unexplained hypercalcaemias.

3 The production of calculi in animals with type-specific bacteria.

4 Tracing of the morphogenesis of aseptic stone arising on calcium plaques or in crystalline clogged pyramidal tubules.

The implication of each of these different approaches remains intensely controversial as a demonstration of a single cause of stone. The author believes that we must revert to the concept that calculus formation is one and only one of many types of crystalline deposition or lithification in tissues. In other words, urinary calculus is not a disease entity but represents a variable physical form of concretum building which may result from equally variable conditions.

Physical chemists teach us that crystalloid-collod aggregates arise when water insoluble crystalline matter is deposited in the fibrillary mesh or organic colloids which are proceeding from the state of sol to that of irreversible gel. The electrodynamic surface action of colloidal matter is of great magnitude and as crystals are caught in the interstices of geling colloids, they undergo changes in form and in polarity with rearrangement internally. This results in a variable increase in density and to some extent determines the ultimate form which the crystalloid-collod aggregate is to assume. Again, this secondary internal crystallization dependent on surface interaction of the forming concretum, determines the lobulation, lamination, Liesegang ring formation, the roughness or smoothness of the surface, the variable densities of surface and inner areas of the stone, and perhaps the size of the concretum itself. The contour of the calculus is, of course, modified by the contour of the calyx or pelvic wall to which it was originally attached. However the electrochemical surface interaction of forming concretums is of the greatest importance even in this respect. Such a physicochemical concept of concretum building explains the polymorphism of stones seen clinically.

Outstanding among the efforts at dissolution of urinary calculi are the use of acid irrigating solutions, such as dilute aqua regia and phosphoric acid, the use of acidifying drugs and diets by mouth, the production of so-called hydrotropic substances in greater concentration in the urine, as in the use of sodium benzoate and glycocholic acid to form hippuric acid by Snapper, Bendien, and Pollak, and the application of calcium-dissolving chemicals such as Al-

GENITOURINARY SURGERY

bright a citric acid sodium citrate solution and Snby's solution of magnesium acid-sodium citrate. The latter seems most popular at present. The reported cases of dissolution or partial dissolution of stone for the most part represented dissolution of soft, pultaceous, calcareous material. However in many roentgenograms illustrating stone disintegration following these techniques few show complete dissolution. Nearly always some calcareous material remains. After a 10 year experience most dissolution techniques have been disappointing. The author has had opportunity to try urinary acidification with intense Vitamin A feeding diets, and drugs. Continuous or rapidly repeated irrigation of stone-bearing and frequently infected kidneys with nephrostomy tubes nephrostomy tubes above and ureteral catheters below tidal irrigators Y tube irrigators, and hand syringe techniques have been used. They are time-consuming and sooner or later lead to renal irritation fever and pyelitis. After all of them were tried the use of the simple Y tube irrigator controlled by the patient with a No. 10 F indwelling catheter has seemed as good a method as any. Tidal irrigators do not work in the renal pelvis with the Munro Nesbit Webb, Snby or other setup. At best, any irrigator must be attached for a number of days or possibly weeks.

When possible stones should be removed surgically or cystoscopically. Residual material or

rapidly reforming calcification may be removed by irrigation. Of the solvents, Snby's solution G is perhaps the best although it too has been only rarely successful.

As stated above soft calcareous material and at times, softer stones can be dissolved. Hard dense calculi of any composition, and especially those with laminations the oxalate and urate stones, defy dissolution by any method used at present. The dangers of urinary acidification especially when prolonged and maintained over long periods of time with ammonium chloride and nitrate are well known. This procedure may even cause stone formation to become more intense. It is therefore the author's practice to apply stone dissolution techniques for a short period of two or three weeks. If they are not well tolerated the regimen is stopped.

The author concludes that our present approaches to stone dissolution are unsatisfactory and the immediate future does not look particularly promising. For this reason, dense calculi those of oxalate and urate composition had better be removed surgically if possible. Efforts at eradication of non removable calculous material should be approached most conservatively with dissolution techniques. Efforts at dissolution of irremovable stones, such as bilateral staghorn calculi which cannot be successfully attacked by the improved extended pyelotomy techniques will rarely be successful.

JOSEPH K. NARAY, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Sheldon, W. H., Thebaud, R. R., Hayman, A. and Wall, M. J.: Osteomyelitis Caused by Granuloma Inguinale. Report of a Case with Cultivation of the Donovan Body in the Yolk Sac of the Developing Chick Embryo. *Am J M Sc* 945:11-137.

During the past year several cases of systemic dissemination of granuloma inguinale have been reported. In this article the authors present the history of a patient in whom hematogenous dissemination of the disease seems to be certain.

A 43 year old colored male was admitted to the hospital complaining of pain and exhibiting a large ulceration on his left leg. His past history revealed that he had had a urethral discharge 20 years previously. This was associated with an inguinal bubo which eventually ruptured and drained for a while. Also about 18 years previously he had an ulcer near the frenulum which healed without treatment. At no time had serologic tests been made, nor had he received any treatment for syphilis.

On admission to the hospital the patient stated that about 6 months earlier he had struck his left shin against a heavy object. The leg was bruised and would not heal. Three months later he injured the same area and an ulcer developed. A month

later the left knee became stiff. Five weeks later a penile lesion was noticed by the patient for the first time. It consisted of a small erosion on the dorsum of the penis adjacent to the corona. He further stated that he had lost 45 pounds in weight in the last six months.

The examination showed an elevated granulomatous lesion measuring 7 by 15 cm. on the upper third of the left leg. A second band-shaped ulcer measuring 1 by 3 cm in width was found encircling the penis just proximal to the corona. There were no lymph nodes palpable in the left inguinal region. Some enlarged nodes were found in the right groin. The laboratory findings were normal except for the sedimentation rate (15 mm. per hour) serum alkaline phosphatase (4.6 Bodansky unit) positive Ducrey and tuberculin tests, and negative Kahn and Frei tests.

A lytic bone defect measuring about 4 cm. in diameter was seen on the roentgenogram of the tibia at the level of the tibial tubercle. The lesion was surrounded by sclerotic bone. Roentgenograms of the other bones were negative except for a cystic lesion measuring about 1 by 1.5 cm. in the anterior portion of the left rib. Biopsies from the granuloma tissue, bone, and bone marrow had the appearance of granuloma inguinale. Donovan bodies were isolated by inoculation of tissue material into a chick embryo yolk sac following the technique described by Anderson. Biopsy of the rib lesion did not resemble granuloma inguinale on histological sections.

The treatment consisted of local application of sulfadiazine and tyrothricin. Fluidin was given intramuscularly at weekly intervals. The tibial defect was packed with iodoform gauze and the packing was changed at frequent intervals. A split thick

Fig. 1. The large granulomatous lesion of the left leg. Note the deep ulceration near the upper edge of the lesion which extended into the marrow cavity of the tibia.

Fig. 2. Roentgenogram of left tibia, lateral and anteroposterior view. Large defect in the tibia with some sclerosis of the surrounding bone and irregular periosteal thickening.

ness graft was applied to the lesion of the leg 90 per cent of the graft survived

GEORGE I. REISS, M.D.

Sallouche, L. G.: A Study of Periscapulothoracic Calcifications (Contribución al estudio de las calcificaciones periscapulothorácicas). *Cirugía y apar. locomotor* 1945 2 239

Periscapulothoracic calcifications are an anatomical form of the periarthritis described by Duplay. They may be acute or chronic. In both the acute and chronic forms the symptoms are pain and rigidity of the shoulder. In some cases there are no symptoms at all. These calcifications are generally located in the subdeltoid and subacromial serous bursae or in the tendon of the supraspinatus muscle the latter localization being the most frequent. They consist essentially of a local calcification caused by an inflammation of the serous bursae which may be due to syphilis or rheumatism or by necrosis of the tendon due to trauma. There is rarely if ever a single severe trauma but usually rather slight and frequently repeated postural or occupational minimal trauma due to pinching of the tendon of the supraspinatus muscle between the head of the humerus and the acromioclavicular process.

The treatment of these calcifications is the same as that of the other forms of scapulothoracic periarthritis. The treatment of choice is infiltration of the stellate ganglion with an anesthetic the author has had good results from the infiltration of procaine followed by the injection of from 2 to 3 c.c. of a 1 per cent solution of novocain. Physical methods such as diathermy infra red rays, radiotherapy and mechanotherapy may be used as adjuvant treatments. If infiltration of the stellate ganglion fails, which has never occurred in the author's experience, forced mobilization should be carried out under anesthesia. Surgical operation is rarely indicated.

The literature on the subject is reviewed and histories and roentgenograms of 7 cases are given.

AUDREY G. MORGAN, M.D.

SURGERY OF THE BONES, JOINTS MUSCLES, TENDONS, ETC

Hellatadius, A.: Bone Chip Grafts in Defects of the Long Bones. *Acta chir scand.*, 1944, 90 317

In some cases of bone transplantation the use of bone chips has proved better than the use of a single large bone graft. For instance, in Albee's operation for tuberculous spondylitis some surgeons have used bone chips in place of the single transplant. Matti believes that the bone chips are more resistant than the large graft to infection in the field of operation.

In this article experiments on rabbits are described in which chips of compact bone (with the endosteum and periosteum) were placed in a defect in the diaphysis of one radius while chips from spongy bone substance were placed in a corresponding defect in the diaphysis of the other radius. On the side on

which compact bone was used new bone was formed more quickly and in larger amounts than on the side on which spongy substance was used and the differentiation of marrow and cortex took place more rapidly.

In some cases the soft parts around the bone showed a tendency to grow in between the spongy bone transplants. It would seem, therefore that chips from compact bone are preferable to those from spongy substance in repairing defects in the long bones.

Matti advocated the use of chips of spongy substance in these cases as he said that the bone cells in the spongy grafts survive while those in the compact grafts do not. This opinion was not confirmed in these experiments.

Further experiments were made to determine the relative value of chips of cortex freed from periosteum and endosteum and chips in which the periosteum and endosteum were retained. Grafts of this kind were inserted into defects in the radius and also into the soft parts around the bone. The experiments showed that new bone is formed more readily when the periosteum and endosteum are retained.

AUDREY G. MORGAN, M.D.

Oldfield, M. C.: Iliaic Hernia after Bone Grafting. *Lancet* Lond., 1945 248 810

On 56 occasions, bone grafts taken from the ilium were used in the repair of defects of the face and skull. One patient developed a Landolt type of hernia of the cecum into the donor site. When the patient was standing a protrusion was noticed in the right flank. The hernia was easily reducible. The hernial orifice was about 1 1/4 inches in diameter and the protruding cecum measured about 3 1/4 inches in its greatest diameter. Repair was done under spinal anesthesia and fascial sutures were used. The fascial strip was taken from the right thigh by means of a Masson's fasciotomy.

The patient was kept in bed for a period of 4 weeks, and during the last 2 weeks graduated abdominal muscle exercises were done. He returned to work and suffered no disability.

GEORGE I. REISS, M.D.

Strange, F. G. S.: The Major Amputation Stump in Health and Disease. *Brit. J. Surg.*, 1945 33 51

The ideal amputation stump is regarded by the author as a smoothly contoured and somewhat tapering cone, well balanced, powerful, with full range of movement, and well re-educatable muscles and of ideal length (as recently described by Kelham and Perkins—*Amputations and Artificial Limbs* London: Oxford Univ. Press 1942). The skin over this stump should be snugly fitting, underlain by its own deep fascia healthy and meeting at a mobile, linear and usually terminal scar.

These requisites will best be attained by the avoidance of trauma at operation, all structures being simply cut through and not subjected to crushing or injections of alcohol as was formerly

done in the case of the large nerve trunks. However a densely adherent nerve end bulb is not necessarily a painful one. The periosteum is cut through level with the bone end. This is almost invariably the site of a spur which must be recognized as a normal constituent of an amputation stump.

Avoidance of infection has also been given much thought however of all the operations designed to heal by first intention, amputation falls most often. Of the 406 cases forming the basis of this report, 332 (81.7%) amputated for a shorter or longer period before healing and this included 79 consecutive cases treated by the author himself with primary healing in 63 (80%). In a clean case, such as the reamputation in which operation can be delayed for several weeks primary suture is permissible. It may also be used in the presence of a septic process, when this process is comparatively remote from the intended site of amputation, when it is of long standing, or when it has not yet developed completely. If however at the time of removal of the tube in 48 hours, there is evidence of infection, the wound must be reopened and the flaps turned back. The delayed suture technique of Jack and Chamley (*British Orthopaedic Association Meeting* Rochester, 1943: 131) is mentioned as an improvement—15 cases healed by first intention, 14 healed with soft tissue infection only, and 3 cases presented severe infections—but still it fell short of the ideal result sought. Secondary suture is performed after 14 days of open drainage of the amputation wound.

There remains, however a proportion of cases in which the infectious process is too close or too acute for any reasonable hope of primary healing following the use of any of the described methods. In these cases the first aid amputation is applicable this is a very low amputation in which some degree of infection is expected, but which allows plenty of room for reamputation when the sepsis has been controlled. The remaining method is the guillotine amputation, which because of the lack of flaps can be carried out very close to the lesion if necessary and thus allows as much room as possible for subsequent reconstruction.

The postoperative management of all the amputations, except the guillotine, was the same: that is, a drainage tube and gauze dressing with tight elastic bandage enveloping the entire stump, were used, and a posterior or other splint was applied for 12 days to forestall subsequent flexion contractures. The drain was removed after 48 hours, and the sutures on the twelfth day no daily dressings, probing or squeezing were resorted to for removal of the hematoma. Nonresistance exercises were begun after 12 days and resistance exercises after 3½ weeks. The stump was ready for limb-bearing after from 4 to 6 weeks.

In the guillotine type of amputation a Bunyan Stannard envelope (*Brit Med J* 1941: 1) is applied and after irrigation with hypochlorite, light skin traction in a Thomas knee splint or Jones humerus extension splint is used on occasion a Thiersch

graft is applied as soon as the bone end is covered by granulations. This method is applicable to the stump which breaks down and leaves an open wound. The striking thing about this Thiersch graft is that it often shrinks down to where it may later be excised with subsequent approximation of the previously nonapproximating skin edges.

In the author's material (406 cases) there were 104 reamputations: these operations are indicated for completion of the two-stage amputations for certain types of adherent scars, for repeatedly identifying scars when there is not enough skin to allow excision and suture, and when there is no stump tolerance of the vascular type. However these operations should wait until the amputation stumps have been healed for 6 weeks. To perform reamputation in the presence of an open wound is a violation of the basic principles of surgery and cannot be condoned even when associated with the use of the sulfonamides or penicillin. JOHN W. BRIDGES, M.D.

FRACTURES AND DISLOCATIONS

Soto-Hall, R.: Fractures of the Carpal Scaphoid. *J Am M Ass* 1943, 129: 235.

The treatment of recent fractures of the carpal scaphoid is almost a solved problem, as has been shown by the many studies of end-results in the last few years; however the author believes that too many surgeons fail, either because they are not vigilant in noting and following the most minute details in diagnosis and treatment or because they experiment with methods which are not founded on sound anatomic principles.

Fractures of this type must be diagnosed immediately after the injury and failure to do so is one of the main causes of nonunion.

The history of a fall on the outstretched hand, tenderness in the anatomic snuffbox, and pain at the point on percussion of the fully extended thumb should be almost conclusive evidence. Should the initial roentgenograms fail to show the fracture, the clinical findings should be used as presumptive evidence, and the only course to be followed is immobilization of the wrist for a period of 3 weeks. After this should radiographic studies again be negative, the patient a ligamentous injury will have been helped by rest, and if as so often happens the films show a bone injury he is already started in the proper path of healing.

Certain precautions in taking roentgenograms are desirable. For careful comparison with the uninjured wrist, lateral views should be taken with the two wrists in the same position, and this can best be attained by putting the palms together with the fingers pointing forward in a "praying position." The posteroanterior views must always be taken in complete ulnar flexion, as in this position the long axis of the scaphoid is visible and at least two obliques are needed to complete the study, with the palmar and dorsal surfaces of the wrist alternately next to the plate. Fractures involving a small part

Fig. 1 Experimentally produced fracture of the carpal scaphoid in a cadaver. A wire has been threaded through the flexor pollicis longus tendon. These views show the intimate relationship of this tendon to the scaphoid particularly to the area of the tubercle. In these specimens any movement of the interphalangeal joint of the thumb produces a definite change of position of the fractured fragments. The tendon passes beneath the transverse carpal ligament and enters the osseoponeurotic canal, of which the scaphoid is a wall then passes distally to be inserted in the distal phalanx of the thumb. Note that in the anteroposterior view the fracture is not visible whereas in the oblique view it is readily seen.

Fig. 2 Two views illustrating maneuver for manipulating the wrist into correct position of full radial flexion, so to 30 degrees dorsiflexion of the wrist with the base of the thumb in full abduction but its metacarpophalangeal and interphalangeal joints relaxed in slight flexion, the heel of the physician's hand pressing against the heel of the patient's hand.

of the proximal pole should be differentiated because in this type the blood supply is poorest and the prognosis therefore is least favorable.

Fracture of the tubercle offers little difficulty since the bone in this area is covered by periosteum and is well vascularized. This is a rare lesion. Full healing should take place in from 3 to 4 weeks by simple immobilization of the wrist.

In the treatment of fractures through the body, the first step should be to determine accurately whether any displacement is present. The lateral film should be carefully studied for angulation. In the presence of displacement reduction can be obtained by traction on the thumb while the snuffbox is molded by the surgeon's fingers. Once alignment has been attained, the fragments can be impacted and properly immobilized by placing the wrist in full radial flexion with from 20 to 30 degrees dorsiflexion and pressing the base of the thumb just below its proximal crease into full abduction.

Proper immobilization of the thumb is important because by its inclusion more complete fixation of the wrist can be attained and any active movement of the thumb involves the long flexor tendon and the abductor pollicis which, by its intimate relationship with the scaphoid produces motion of the fragments.

Care must be taken to force the thumb into abduction at its base rather than at its tip since the latter procedure leads either to strain or to subluxation of the metacarpophalangeal joint. In this strained position recovery of function takes place much more slowly. The metacarpal therefore should be abducted and the thumb relaxed in slight flexion.

An anterior skin-tight plaster splint is first applied and then one layer of circular flannel bandage is wrapped around the extremity. This is followed by

a circular plaster splint. It is important that the plaster be carried as close to the elbow as possible and still allow full flexion of this joint and as previously mentioned the plaster should extend to the middle of the thumb nail and to the metacarpophalangeal joint of the fingers. Mobilization of this area in scaphoid fractures will not produce the stiffness one always notes following Colles' fractures.

Immobilization should be complete and undisturbed for at least 6 or 10 weeks. A large percentage of fractures will heal in this time but a period of from 4 to 5 weeks longer may be necessary. Roentgenograms and clinical examinations should determine whether this further immobilization is desirable. The presence of local tenderness in the anatomic snuffbox, or pain on percussion on the tip of the thumb associated with inconclusive radiological evidence of union should warrant further immobilization. Sometimes the clinical evidence of union will appear before it is demonstrated in the roentgenogram.

Certain authors have recommended prolonged immobilization sometimes as long as from 12 to 18 months. The author does not concur with this policy, because 95 per cent of fractures will have united in from 4 to 5 months and when union is delayed beyond that time there are certain complications which should be treated surgically rather than by further splinting. These are malposition of the fractures, interposition of strong fibrous bands, aseptic necrosis, or an uncontrolled very small fracture of the proximal pole. In the latter injury in which only one-sixth of the scaphoid is involved an excision of the small fragment (if three months splinting fails) results in better function than very prolonged immobilization.

When fractures of the scaphoid are associated with luxation of the semilunar bone, which occurs in about 12 per cent of the cases, the wrist must of necessity be held in slight volar flexion for the first 4 weeks. If it is placed in dorsiflexion in order to treat the scaphoid fracture the semilunar may redislocate.

ROBERT P. MONTGOMERY, M.D.

Pendergrass, E. P., and Lafferty, J. O.: Roentgen Study of the Ankle in Severe Sprains and Dislocations. *Radiology* 1945 45 40.

Usually the interpretation of roentgenograms of the ankle is confined to the diagnosis of bone or cartilage lesions because it is based only on anatomical observations. The present article represents an attempt to employ roentgenography for the diagnosis of soft tissue lesions of the ankle by taking into consideration the physiology of this joint.

The authors noticed that multiple roentgenograms of a recently severely sprained ankle which was manipulated into different positions on the roving table showed an abnormal lateral rotatory mobility of the talus and a tendency of the talotibial joint to subluxate, whereas films of 6 normal ankles failed to demonstrate this phenomenon. After four weeks of immobilization this abnormality could no longer be demonstrated. (The case was complicated by an old ununited fracture of the internal malleolus which was thought not to have any bearing on this observation.)

The authors come to the conclusion that in cases in which conventional anteroposterior and lateral films of the ankle in neutral position fail to show any bone lesion, additional anteroposterior films should be taken with the foot held in forced inversion and eversion as well as in flexion and extension. This type of filming is also recommended for cases of recurrent painless ankle sprain, instability of the ankle, abnormal mobility of the ankle joint with a depression in front of the external malleolus and for cases which are to be given procaine injection treatments. The purpose of this examination is to demonstrate a tear or extreme stretching of the entire external lateral ligament, or at least of its anterior and middle fascicles. In simple sprains only the anterior fascia is involved according to Elmle. No x-ray findings are then to be expected.

Permission for the manipulation of the ankle necessary for this type of filming should be obtained from the referring physician. The injection of from 5 to 10 c.c. of procaine around the point of maximal tenderness prior to the examination is suggested for painful cases.

GERHART S. SCHWAB, M.D.

Cano, L. S., and Valdés, E. R.: Mechanical and Biological Problems in Nailing the Marrow of Fractured Bones by Kuentscher's Method (Los problemas mecánicos y biológicos del enclavamiento modular de Kuentscher). *Cirugía após locomotor* 1945 3 93.

The history of the method of inserting metal nails or pegs into the marrow cavity in fractures of the

long bones is reviewed. Various metals were tried but in 1940 Kuentscher described his method of using V-shaped inserts of stainless steel, which seems to be the best method so far devised. With the use of this metal there is no corrosion and immobilization is so complete that the use of plaster is not necessary.

This method fulfills the three requirements in the treatment of fracture that the fragments be accurately reduced, that they be immobilized in good position until consolidation takes place, and that the muscles and joints be exercised as much as possible during the immobilization of the fragments. It has been found that the presence of a large foreign body in the marrow cavity is tolerated very well and that the pressure exercised by the nail further calls formation. The marrow itself also plays a part, but not the predominant part, in callus formation. Callus formation takes place for the most part from metaplasia of connective tissue. The presence of the nail may stimulate callus formation by a process of chemical irritation and by stimulation of phosphatase production, although the authors have not been able to demonstrate the latter.

The blood picture usually shows a more or less marked eosinophilia and an increase of reticulocytes for some days after the insertion and removal of the nail. Experimental work has shown that some bit passes into the lungs but not enough to endanger the life of the patient. Infection is rare in these cases and when it occurs, it is mild.

The chief indication for the use of this method is in simple fractures of the diaphysis of the femur, especially in elderly patients in whom continuous extension or plaster casts are dangerous. It is also very useful in corrective osteotomies, in viciously consolidated fractures, and malformations of the joints. It is not so definitely indicated in compound fractures, gunshot fractures, and fractures of the tibia, humerus and forearm.

Thirteen cases treated by the authors are discussed, 6 being simple fractures of the femur; 1 a pathological fracture of the femur from metastatic carcinoma, 3 simple fractures of the tibia, 1 a compound fracture of the tibia, 1 a pseudarthrosis of the humerus, and 1 a pseudarthrosis of the radius.

AUBREY G. MORRIS, M.D.

Rodríguez, F. D.: The Surgical Treatment of Pathological Fractures (Tratamiento quirúrgico de las fracturas patológicas). *Rev. aspa. de cirugía ortopé.* 1945, 73: 17.

When fragility of bones is due to general causes and the whole skeletal system is involved the treatment is chiefly medical, but when bone disease is caused by localized infections or cysts the resistant fractures can be treated surgically. In such cases there is a localized rarefaction of bone and always a deficiency of protein. One of the principles of treatment is to remove the periosteum, together with fragments of cortex, of a normal part of the bone, and add these fragments to the blood clot which has formed at the site of the fracture. This provides a

medium for fixing the calcium phosphates and initiating regeneration of bone. Blood calcium is an important factor in osteogenesis.

Two cases are described the first in a young woman who suffered a fracture of the middle third of the left humerus merely from her husband taking her arm. The bone could be doubled back on itself at the site of the fracture without any pain. The roentgenogram suggested hydatid cyst and this diagnosis was confirmed by biological tests. The cyst was destroyed by surgery and for some days destruction of the parasites was continued chemically by means of a mild solution of formal introduced into the marrow cavity of both fragments through drains. When all the echinococci were thought to be destroyed hyperemic treatment was begun with short waves hot fomentations and Bier's passive congestion. During the days that this treatment was given the site of the lesion was irrigated daily with rivanol solution to maintain an acid reaction. When the roentgen and clinical pictures suggested that osteogenesis had begun, an alkaline solution was substituted for the acid one. (Mineralization of the protein substance is best brought about in an acid medium.) When osteogenesis was at its height a plaster cast was applied and the patient sent home. After 6 months she returned with a completely consolidated fracture and good function of the arm but the bone had healed in a vicious position.

The second case was that of a young girl 12 years of age with a cyst which was caused by localized osteitis. This case was treated by the insertion of a nail into the marrow cavity of the two fragments (Kuehntscher's method). The fracture was in the upper third of the femur. Fixation was perfect and

after a week the patient could move the joint, and after 25 days she was able to get up and walk. This treatment avoided the muscle atrophy and rigidity of the joint which is sometimes caused by prolonged rest.

The article is illustrated with roentgenograms of both cases and photographs of the second patient showing the excellent results of treatment.

AUDREY G. MORRAN, M.D.

ORTHOPEDICS IN GENERAL

Hertz, R.: Herniation of Fascial Fat and Low Back Pain. *J Am M Ass* 1945 128 931

The author reports the cases of 6 female patients with low back pain who recovered completely following the removal of a tumor in the low back region. The tumor consisted of a fat hernia through the superficial fascia in the lumbar and gluteal areas. In most instances histological examination of the excised fatty mass revealed fat lobules and some fibrous tissue. The blood vessels showed perivascular proliferation, thickened walls and congestion.

In many of the cases several nodes were palpable in the lower back region. Injection of 1 per cent novocain into the small hard masses alleviated the low back pain. Some patients complained of pain in the left or right leg associated with the low back pain and this pain also disappeared when the novocain injected into the nodes had localized in the low back region. All patients who responded favorably to the local injection of novocain had complete relief after the nodes had been excised.

Copeman and Ackerman report similar findings in 14 soldiers with back pain.

GEORGE L. REISS, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Crafoord, C., and Nylin, G.: Congenital Coarctation of the Aorta and Its Surgical Treatment
J. Thorac. Surg. 1915 14 317

It was demonstrated by one of the authors in an experimental study on dogs that the flow of blood to all the organs could remain suspended for as long as twenty to thirty minutes without any subsequent signs of organic damage provided an adequate flow of blood was secured. This circulation to the brain was maintained by creating anastomoses between the carotid and jugular vessels of an animal of the same size. On the strength of this observation Crawford in certain patients with a patent luctus arteriosus took the risk of placing clamps on the aorta at the level of the duct. Although in one of the patients this part of the operation took 37 minutes to perform, no noticeable disturbances were observed in the patient's internal organs.

The question arises as to whether it might not be possible to treat congenital coarctation of the aorta by a purely surgical means. Coarctation of the aorta is a fairly common abnormality and knowledge of the congenital defect really has accumulated in the last few decades. The anomaly has been known for nearly 200 years. In her classical work on congenital cardiac disease Abbott found 132 cases among 1,000 cases of congenital cardiovascular defects.

The constriction of the aorta is localized just below the insertion of the duct arteriosus. The narrowing may be very slight or there may be complete obstruction of the aorta. The aorta is not usually dilated above the constriction but the part proximal to the obstruction may be thin walled and hypertrophied. The descending aorta is of the same size as the upper portion but very often it is partly obliterated. The deformity is often associated with other cardiovascular anomalies such as bicuspid aortic valves. Anomalies of the aortic arch are frequently found.

Coarctation of the aorta in its classical form is easily recognized. The most important sign is the increased blood pressure in the upper part of the body. Some cases of coarctation may occur however with normal blood pressure in the arms. Every young person with hypertension should be examined at first to find out if he has a coarctation. If he has no pulsations in the popliteal artery or if the blood pressure is lower in his legs than in his arm then it should be realized that there may be coarctation. In general the average age at death in Abbott's series was 32 years.

The authors report 2 cases, one of a 12 year old boy and the other of a 27 year old farmer both of

whom were operated on to relieve congenital coarctation of the aorta. The details of the findings before and after the operation are presented. In both patients the aorta showed conical narrowing from the origin of the subclavian artery and the real constriction between the coarctation and the point of junction of the subclavian artery was much lower in the boy than in the farmer.

When re-examined about 6 months after operation both patients were in excellent health. The boy returned to school and the farmer worked at home. In the first case the systolic blood pressure in the left arm was 130 mm. Hg. and the diastolic pressure was 80. In the left leg the systolic pressure was 130 and the diastolic pressure 80 mm. Hg. In the second case the systolic blood pressure in the left arm was 145 and the diastolic pressure was 90 mm. Hg. In the left leg the systolic pressure was 120 and the diastolic pressure 80 mm. Hg.

It is remarkable that in both cases normal coarctation was established. The lives regarding the blood pressure in the legs was a little higher than in the arms and no hypertension was present. This postoperative effect is of considerable interest and is in favor of the mechanical theory of hypertension in coarctation.

Agar, J.L., Rawlands, J., and Odell, W.: Iliac Arterial Aneurysm following Injury to Iliac Vein.
Brit. M. J. 1915 2 455

The 2 cases reported by the authors are examples of arterial aneurysm following war wounds. In each case laceration of more than one iliac artery was necessary. The operations were accompanied by profuse and rapid hemorrhage to combat which profuse and rapid transfusion was necessary. Recovery was undoubtedly due to the promptness and completeness with which the blood loss was made good.

In each of these patients the surgeon was faced during the course of the operation, with hemorrhage at a rate with which transfusion could not possibly keep pace and the only way in which an immediate fatal issue could be avoided was by the application of a temporary packing and interruption of the operation until the circulatory volume had been restored to a reasonable level.

Detailed clinical histories and the findings in the 2 cases are presented—an aneurysm of the buttock in the first patient and a retroperitoneal aneurysm in the second patient. In the first case 14 pints of blood and 4 pints of plasma were given during the operation and a total of 27 pints was given during the first 4 days, from which there was no reaction.

In commenting the authors note that in the one case in which both internal iliac arteries were tied, the pelvic organs which should have suffered mani-

mum deprivation did not reveal evidences of damage. The heel, supplied by the external iliac artery which was not tied, showed arterial gangrene.

In the second case the nutrition of the limbs never seemed to be in danger even though not merely all the iliac arteries but the epigastric anastomosis which forms the most obvious collateral channel had been tied. The details of the operation for the repair of the retroperitoneal aneurysm are presented.

The authors note further that one of the most striking advances in surgery during the last 4 years is the progress that has been made in the use of whole blood. The advantages of an adequate blood bank for needed massive transfusions are pointed out and described. While blood transfusion undoubtedly has its dangers, these dangers are associated with the giving of blood to those who are gravely ill and who have been repeatedly transfused over a long period. Blood from a blood bank, properly prepared and given, seems to have no dangers in the type of massive post-traumatic hemorrhage in which it offers the only means of saving life.

HENRY F. THURLOW, M.D.

Zakerman, C. M.: Thrombophlebitis of the Cubital Veins in Blood Donors. *West J Surg* 1945 53 311

Among approximately 285,000 venepunctures performed at the Blood Donor Center, Chicago, Illinois, there was found to occur 12 cases of thrombophlebitis in the cubital veins following venesection. Of these 12 were in females and 1 in a male. The most important predisposing factors are listed as trauma to the vein wall and slowing of the blood flow by means of (a) the application of a circular bandage (b) hematoma, (c) systemic reaction (d) acute flexion of the forearm or straining of the arm during exercise following venepuncture.

Disability following thrombophlebitis of the cubital veins averaged approximately 4 months.

The best preventive measures are listed as follows:

1. Careful venepuncture technique.
2. The immediate discontinuance of the bleeding if a hematoma develops or if the donor complains that the needle causes discomfort.
3. Preventing the donor from flexing his forearm after venepuncture.
4. A circular bandage should not be applied as a dressing.

Eight of the donors mentioned had given blood for the first time and 4 were repeat donors. 7 of the donors developed hematoma. 5 donors were bled at the Fixed Center and 7 were cared for on the Mobile Units.

The author presents a table giving the essential data on the 12 donors who developed thrombophlebitis.

RICHARD J. BENNETT JR., M.D.

Silbert, S.: Thromboangitis Obliterans. *J Am M Ass* 1945 129 5

The criteria for the differential diagnosis between thromboangitis and arteriosclerosis in patients be-

tween 40 and 50 years of age are given as follows:

Thromboangitis obliterans

- Patient appears younger than his age
- Hair normally pigmented
- No arcus senilis
- Retinal arteries normal
- Blood pressure usually low
- Radial and temporal vessels soft
- Upper extremities frequently involved
- Femoral arteries frequently closed
- No calcification of vessels on x-ray examination
- Blood volume usually diminished
- Symptoms of coronary artery sclerosis rare
- Aorta appears normal on x-ray examination
- Albuminuria rare
- History of migrating phlebitis frequent

Arteriosclerosis

- Patient appears older than his age
- Hair usually gray
- Arcus senilis frequently present
- Retinal arteries usually sclerotic
- Blood pressure often high
- Radial and temporal vessels thickened and hard
- Upper extremities seldom involved
- Femoral arteries seldom closed
- Calcification of vessels on x-ray examination frequently seen
- Blood volume usually normal
- Symptoms of coronary artery sclerosis frequent
- Aorta sometimes appears elongated on x-ray examination

Albuminuria not uncommon

History of migrating phlebitis rare

One hundred patients with thromboangitis obliterans have been followed up for more than 10 years. All of them stopped smoking at the beginning of treatment and have not resumed since.

In all of the patients the disease has remained completely arrested following the initial period of treatment.

Thromboangitis obliterans is caused by smoking in individuals constitutionally sensitive to tobacco.

JOHN J. MALONEY, M.D.

Chapman, E. M., and Linton, R. R.: Mode of Production of Pulmonary Emboli. *J Am M Ass* 1945 129 196.

The authors believe that acts of straining such as holding the breath in inspiration and making an expiratory effort with the glottis closed, especially by those confined to bed from illness or operation, commonly result in sudden and often fatal pulmonary emboli.

The dramatic plugging of the pulmonary arteries by clots released from the leg veins after straining on a bedpan has been witnessed probably more often by nurses than by doctors.

There is a rise of several centimeters in the arm vein pressure during the forced expiratory effort with the glottis closed. The difference between this reading and the reading in the leg when the patient is recumbent is probably due to the fact that the

venous reservoir drained by the superior vena cava is much smaller and more subject to pressure by muscles and other structures. However when the patient is sitting in the bedpan position there is a great rise in the normal venous pressure in the legs (hydrostatic effect) and this in turn shows a greater increase on forced expiratory effort.

The release of mural thrombi that so often lie in the leg veins is due to the fact that the venous pressure and volume in the leg rise sharply during forced expiratory effort with the glottis closed. A clot located with this rise in the venous pressure there is a temporary impeding of the return of the blood to the heart, so that the peripheral veins become distended with blood, and this may loosen an imbricately attached mural thrombus. With the drop in venous pressure during the next inspiration the dammed venous blood rapidly empties from the peripheral veins which hang with it any loosely attached thrombus.

STEWART A. ZIEGLER, M.D.

Hampton, A. O., Prandoni, A. G., and King, J. T.: Pulmonary Embolism from Obsolete Sources. *Bull. J. A. S. Hosp. et H. p.* 1915 75 235

Ten cases are reported in which acute chest conditions appeared to have been caused by pulmonary embolism, with or without infarction. The emboli originated from various venous sources in ambulatory active individuals. Careful examination failed to show any signs of heart disease or of vascular disorders prior to the first embolic episode, with one exception. In 3 patients the source of embolism never became clear. No specific common factor was noted that could reasonably be supposed to have caused phlebotrombosis and embolism was elicited. There were 8 army officers in the group, which suggests that exertion may be a factor. At the time of admission there was no obvious sign of venous thrombosis except in one patient who had a thrombosed hemorrhoid. Accurate diagnosis in such cases is exceedingly difficult at the onset and none of the patients was admitted with a correct diagnosis. One was thought to have primary atypical pneumonia, 1 pericarditis with effusion, 1 ruptured peptic ulcer, 1 metastatic carcinoma of the lung, 1 angina pectoris, and 3 were thought to have coronary occlusion.

Röntgenograms of the chest are not very helpful at the onset since the shadow of infarction does not develop until a day or two have elapsed. In general dyspnea was more prominent than pain. A dull pain in the base of the neck or in a shoulder followed by pain in the axilla, should suggest pulmonary embolism. Elevation of the temperature within twenty-four hours of the first symptom is more suggestive of embolism than of coronary occlusion. Blood spitting occurs in less than half of the cases and then only after infarction has occurred. The most difficult differentiation is between embolism from a silent peripheral source and embolism from myocardial infarction. Serial electrocardiograms and phlebograms usually elucidate the diagnosis. The authors

found phlebograms very helpful in the diagnosis and had no serious results from the procedure. Criteria for the interpretation of phlebograms, roentgenograms, and electrocardiograms are recorded.

The treatment consisted of heparin and dicumaril anticoagulant therapy plus rest and elevation of the part affected by thrombosis or phlebitis.

JOHN L. LIVINGSTON, M.D.

Golodner, H., Morse, L. J., and Anglist, A.: Pulmonary Embolism in Fractures of the Hip. *Surgery* 1915, 18 418.

A patient who suffers a fracture of his hip presents ideal conditions for the development of venous thrombi in the lower extremities. The blood stream is slowed by the complete voluntary immobilization of the extremities to avoid painful movements at the fracture site by the associated reflex vasospasm induced by the fracture and by the impaired cardiac circulation and the inadequate peripheral circulation.

In the aged group. Concomitantly changes in the chemical composition of the blood conduce to thrombus formation as a result from the liberation of toxic ferment by the lacerated muscles, ligaments, and nerves at the fracture sites. Initial damage occurring when the patient is bedridden is enhanced when splints or Wilkie boots are utilized because of the greater pressure exerted against the calf veins by these plates of Dan encasement.

The most dangerous type is the "phlebotrombosis" or silent propagating thrombus because it lacks local symptoms and therefore a precaution is overlooked. The insidious silent propagating venous thrombus was predominant in Golodner's series. Not one patient gave any symptoms reflecting the presence of venous thrombosis in the lower extremity. As a rule some effort motion discharged the fatal pulmonary embolus in 1 case it was manipulative reduction in the operating room. In another transfer of the patient from a bed to a wheel chair in others turning the patient from one side to the other in bed. Deaths occurred as early as the sixth day and as late as the seventieth day following injury.

The occurrence of venous thrombosis and embolism is less frequent in patients who are made ambulant early and prophylactic bilateral superficial femoral vein ligation combined with lumbar sympathetic block is suggested as being most ideal for the prevention of pulmonary embolism in fractures of the hip especially in those who cannot be made ambulant early. STEWART A. ZIEGLER, M.D.

Gaston, E. A., and Felson, H.: Ligation of the Inferior Vena Cava for the Prevention of Pulmonary Embolism. *J. F. Med. J.* 1915 33 229.

The literature on vein ligation for the prevention of pulmonary embolism is reviewed. Femoral vein and common iliac vein ligations are discarded. Ligation of the inferior vena cava seems desirable, first to interrupt the venous channel above the en-

dent femoriliac thrombosis and second to prevent embolism from a simultaneous subclinal phlebotomy that is frequently present in the veins of the opposite lower leg.

Although it seems evident in a great majority of cases that pulmonary embolism arises from venous thrombosis originating in the vein of the lower legs and later progressing upward to involve the pelvic veins there are some cases in which the thrombotic process arises in the pelvic veins themselves.

Numerous reports of experimental rapid occlusion of the inferior vena cava by ligation have been published, beginning with the work of Lower in 1669. It has been repeatedly and conclusively shown that ligation above the level of the renal veins results in death, usually with accompanying anuria and uremia. Below the level of the renal veins experimental ligation of the inferior vena cava is compatible with life carries a low mortality rate and is associated with only slight and transient edema of the lower extremities.

The authors have reviewed clinical reports of inferior vena cava ligation in man and state that ligation of the inferior vena cava below the level of the renal veins although an operation of considerable magnitude is compatible with survival in both experimental animals and man.

Two cases are presented to illustrate situations in which an operation was followed by recovery. At the time of caval ligation both patients had suffered multiple pulmonary infarcts. Both had had previous common femoral vein ligation, bilateral in the first case and on one side only in the second case. Caval vein ligation was performed under spinal anesthesia supplemented by sodium pentothal in one case through a right rectus incision. The inferior vena cava was ligated in continuity with two nonabsorbable sutures 1 cm. apart at the level of the bifurcation of the aorta.

Mottled cyanosis of both legs was noted immediately after operation followed by pitting edema which came on in 4 hours. However there was gradual subsidence of this and 4 months after operation there was no edema in the first case and only minimal edema of the left leg in the second case.

The following points are considered most helpful in sustaining the patient through the critical post-operative period: swathing the feet, legs and thighs tightly in elastic bandages to help prevent shock due to the rapid withdrawal of edema fluid from the circulation; the early use of oxygen and adequate intravenous infusions of plasma and whole blood.

LUCIAN F. FROWDOTI M.D.

BLOOD TRANSFUSION

Britton C. J. C. and Warner C. P.: Leucemoid Blood Reaction Simulating Acute Aleuemic Leucemia in a Case of Phlegmonous Gastritis. *Lancet* Lond. 1945 249 430.

A case is reported wherein apparently the blood picture reaction to a phlegmonous gastritis so closely

resembled that of an acute aleuemic myeloblastic leucemia that the correct diagnosis was not made during life. The patient was a single woman aged 47 who developed a sore throat cold and temperature. After five days of treatment with a sulfonamide (identity and dosage unknown) she vomited. This illness was followed by weakness and an apyrexial symptomless period of about 10 days then the patient developed a high temperature headache and a slight cough, drowsiness, slow cerebration and pale mucous membranes and heavily coated tongue. The liver was palpable $1\frac{3}{4}$ inches below the costal margin and soft glands could be felt in the posterior triangle of the neck and in the groin. At this time the blood picture exhibited a total white count of 3,700 with a paucity of polymorphs (5.5%) and a large number of myeloblasts or promonocytes (45.0%). The lymphocytes amounted to 35.5 per cent there was only one normoblast but numerous platelets were found. Ten days later the blood picture showed a white count of 2,600 4 per cent of polymorphs 17 per cent of myeloblasts and 77 per cent of lymphocytes and 8 days later the picture was that of a leucopenia with 1,400 white cells with 8 per cent of polymorphs, 50 per cent of myeloblasts and 40 per cent of lymphocytes.

The patient did not at any time show material improvement in her condition under the picture of an anemia, hyperpyrexia, weakness and mental confusion she died a month after the onset of the illness.

Autopsy showed no evidence of leucemia in any organ. In the bone marrow there was a moderate increase in the erythroblastic and myeloid tissue but no myeloblastic reaction was noted. The most striking finding was an acute phlegmonous gastritis with ulceration and gangrene low grade peritonitis and bronchopneumonia were also present.

Since the clinical findings all pointed to a diagnosis of acute aleuemic leucemia and the patient was obviously dying when she came under the authors' attention, confirmation of the diagnosis by means of a splenic puncture was not considered necessary and therefore the autopsy findings were a complete surprise.

JOHN W. BRENNAN M.D.

Thierach J. B.: Attempted Transmission of Human Leucemia in Man. *J. Lab. Clin. M.* 1945 30 866.

Whereas in fowls and mice leucemia can readily be transmitted in susceptible strains and only a minimal amount (one leucemic cell) of leucemic material is necessary for a successful transmission all attempts of previous workers and the ones described herewith to transmit this condition in man have failed. So far no transmission of leucemia from man to man, by means of blood, lymph node or spleen, has been established. The reason for this failure might be sought in the following factors.

The technique employed. The assumed leucemic agent might not be able to contact sufficient susceptible cells of its own type that is cells of the bone

marrow or lymph nodules, by the subcutaneous or intravenous routes, which were employed for the attempted transmission. The agent of human leucemia might be extremely sensitive and not survive the procedure of transmission.

The material used. Whole blood lymph nodules and spleen might not be suitable for transmission in that they might either contain no leucemic agent or have it only in an inactive form.

The time of observation. The time of observation in many cases was certainly very short but even 2 months might not be sufficient time for the agent to establish itself and produce a leucemia.

The choice of hosts. Only people with a life prospect of under two years were available and all suffered from incurable diseases, the recipients could not be regarded as "virginal organisms." These patients might have had sufficient antileucemic factors to prevent a take.

The recipient might also have had a natural immunity might have belonged to a non-susceptible strain of man, or might have had an acquired immunity which protected him against any leucemic agent.

It also might be that human leucemia, contrary to animal leucemia, cannot be transmitted and therefore all attempts at transmission were useless from the start.

The fact that even material from acute leucemias would not produce reactions in the recipients is remarkable as one would expect that this type of leucemia with its fulminant course would be the easiest to transmit.

Of all the factors mentioned, the difficulty of obtaining suitable hosts and the apparently unexplained route were the most important and might certainly have been responsible for the negative results of the transmission attempts. *By JAMES COLLIER, M.D.*

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Fomon, S. L. Nongro, R. Schattner, A., and Turchik, F.: Cancellous Bone Transplants for the Correction of Saddle Nose. *Ann Otol Rhinol* 1945 59: 518.

An ideal nasal transplant should be readily available in sufficient quantity and have a consistency that will permit easy modeling. It must resist infection and absorption, be well tolerated by the tissues, and not subject to change in shape after implantation. While a graft meeting all of these specifications is still being sought the authors believe that at present cancellous bone obtained from the ilium is the material of choice. Next to cancellous bone, cartilage is probably the most satisfactory material for nasal grafts but it has certain undesirable qualities not encountered in grafts of cancellous bone. It is prone to curl and its failure to form an organic union with the nasal bones, to which it becomes united only by means of fibrous tissue frequently leads to an unnatural mobility.

In preparing for the operation a cast is made of the nasal defect and from this a stent is built up to the normal contour. This model is sterilized at the time of operation to aid in the shaping of the transplant. The first step in the operation is the preparation of the bed which is to receive the transplant. A circumferential incision is made in the left vestibule along the lower lateral cartilage and through this the soft tissues are separated from the dorsum of the nose. At the upper end the periosteum is undisturbed for the reception and immobilization of the tapered end of the proposed transplant. If a columellar strut is needed an incision is made along one side of the membranous septum and through this a bed is made in the columella between the two mesial crura.

The surgeon and assistants then change gown and gloves and freshly sterilized instruments are supplied to prevent cross-contamination as the transplant is obtained. The iliac crest is exposed through a curved incision and the periosteum and a thin layer of cortical bone are then resected from the bone of appropriate size is then removed. To prevent splintering the graft is undercut with a thin broad chisel first on one side and then on the other in an oblique manner so that the cuts will meet beneath the center of the graft at the required depth. No attempt should be made to elevate the graft until it lies free in its bed. A motor driven saw is not recommended in this procedure because it is believed that the heat which it engenders tends to impair the viability of the bone.

The graft is then shaped in accordance with the pattern made from the cast. The upper end is taper-

ed to a thickness of from 1 to 3 mm. so that it will fit easily into the perioskeletal socket at the nasal root. The lower end is tapered to blend with the tip. It is then inserted into the prepared bed. Any blanching of the skin over the graft indicates too great tension upon the surrounding soft parts and under such circumstances either the graft must be removed and made smaller or the soft tissues must be undercut sufficiently to assure tensionless reception of the transplant. The incision is closed with atraumatic sutures and the nose loosely packed with vaseline gauze. The graft is held in position externally by narrow strips of adhesive tape applied around the tip and over the bony dorsum. To protect the nose against trauma and minimize postoperative edema a stent dressing is firmly applied and held in place with adhesive strips.

The authors have used cancellous bone for nasal grafts during the past three years and have found it far superior to other material used for this purpose.

JOSEPH J. McDONALD, M.D.

Barley O. T. Ingraham, F. D., Swenson O. Lowrey J. J. and Bering, E. A.: Human Fibrin Foam with Thrombin as a Hemostatic Agent in General Surgery. *Surgery* 1945 18: 347.

This article records the findings and results of carefully planned experimental and clinical investigations, and the conclusions reached are based upon controlled pathological and clinical observations in a sufficient material.

In 5 monkeys, lacerated wounds of the liver were packed with fibrin foam with thrombin; the wounds were sutured and examined at intervals of 30 minutes 4 hours and 21, 70 and 74 days.

In 4 monkeys a 1 cm. cube of fibrin foam soaked in human thrombin solution was inserted deep in a stab wound of the liver. The wounds were sutured and examined after an interval of 11 and 16 days, and 8½ and 12 weeks. This procedure was repeated in conjunction with the hemostatic materials and the specimens were examined 8 days and 5½, 8, 9 and 12 weeks later. In another monkey this procedure was repeated except that a cube of fibrin foam with thrombin that had been dipped in penicillin was placed in a second stab wound. This animal was sacrificed 34 days after the operation.

In 5 monkeys a cube of fibrin foam with thrombin was placed between the traumatized liver and the diaphragm and the animals were given an autopsy examination at 3 (2 animals) 4½, 8 and 12 weeks. This procedure was repeated with the variation that the fibrin foam, after soaking in thrombin was rolled in sulfadiazine powder and the autopsies were done at 5½, 8 (2 animals), 8½ and 12 weeks.

In 3 monkeys, which were sacrificed 3, 7 and 13 days respectively after operation two stab wounds

cubic centimeter or higher. With intramuscular dosage, the 2 hour penicillin level is almost always below the *in vitro* sensitivity of the organism. Thus therapy may be ineffectual for a significant portion of the time between injections. Besides, many patients do not tolerate fractional intramuscular injections. The necessity for frequently repeated injections will also interfere with the rest of the patient.

The authors believe, therefore, that the fractional intramuscular method of penicillin administration can be recommended in the treatment of disease due to bacteria which are highly susceptible to the action of penicillin, and when the span of the treatment is relatively short as it is in gonorrhea and pneumonia.

The method of continuous intramuscular infusion is technically simple. Its maintenance causes serious complaint from the patient. The thigh muscles of the average patient were found to tolerate only 750 c.c. of solution per day. More than this resulted in acute muscular soreness and necessitated discontinuance of the infusion. Besides, in the same penicillin concentrations following the continuous intramuscular drip tended to be consistently lower than those obtained by the continuous intravenous drip.

The method of continuous intravenous drip is technically more difficult than fractional or continuous intramuscular dosage. The use of 23-gauge needles and the utilization of veins about the wrist or arm, and legs overcome many of the difficulties. This method causes minimum discomfort and is well tolerated.

The incorporation of heparin in the venoclysis is believed of value in continuous intravenous therapy. It is possible to keep the drip at a single site every 3 or 4 days. The high serum levels thus obtained make it possible to attack infections hitherto considered inaccessible to penicillin therapy. Extreme resistance of an infecting agent should no longer be a deterrent to attempts at penicillin treatment. Massive dosage even up to 10,000,000 units per day does not produce symptoms of toxicity.

SAMUEL KAREN, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Harvey E. N., Butler E. G., McMillen J. H. and Puckett, W. O.: Mechanism of Wounding
Il or Med., Chic., 1945 8 9

High velocity missiles have been observed by means of high speed moving pictures (from 2,000 to 7,000 frames a second) showing the movement of the missile in water and gelatin gel. Roentgenograms taken with a one millionth second exposure demonstrate that similar changes occur in living tissues of anesthetized dogs and cats. This investigation exhibits shock waves in tissues, the formation of a

very large temporary cavity which pulsates several times before subsiding, a region of extravasated blood and a permanent cavity larger than the cross sectional area of a missile.

In general, it can be stated that the effect of penetration of a high velocity missile is analogous to that of a little explosion within the tissue.

The article is accompanied by 17 figures showing the successive steps of the penetration of a missile and microsecond roentgenograms of missiles passing through tissues and substances.

RICHARD J. BENNETT, JR., M.D.

Young, M. W.: Mechanics of Blast Injuries
Il or Med. Chic. 1945 8 73

During the present war some antipersonnel mines and concussion bombs were preceded by pilot bombs, screeches, noise makers, buzzes, or even sirens and these were apparently designed to produce a reflex contraction of the voluntary muscles of the body and thus, in turn, produced an initial increase in venous and cerebrospinal fluid pressure. Voluntary muscle contraction will produce an increase in venous pressure. An increase in venous pressure is transmitted to the cerebrospinal fluid. When an actual bomb explosion follows the preliminary noise, persons nearby to voluntarily contract all their muscles thus raising the venous pressure when the actual explosion occurs this increased venous pressure is again greatly increased by the sudden explosion which causes a wave of increased atmospheric pressure. This concussion wave causes a sudden increase of atmospheric pressure surrounding the body and it produces an increased pressure on the body and its fluids. Sailors undergo a similar experience when caught by the water concussion wave of a depth charge. When applied to the body this increased pressure may be as much as several atmospheres. The pressure on all the body surfaces and fluids is increased except within the craniovertebral space which is protected from external forces by a firm bony globe. The pressure within the cranium at the instant of increased atmospheric pressure is for other areas is literally squeezed into this low pressure area in the cranium. The cranium becomes quickly filled with fluid and then experiences the maximum force of the external pressure.

Experiments were carried out in which preliminary ligations of the jugular veins were done, and the sudden external pressure was applied. It was demonstrated that preliminary ligation of the jugular veins will almost completely prevent the increase in intracranial pressure. From the practical standpoint when preliminary noises give warning of an impending explosion, it would be to the individual's advantage to be taught to compress his jugular vein rather than cover his ears by so doing he is able to protect his nervous system from the greater compression soon to follow.

Radgett, E. C., and Gaskins, J. H.: The Use of Skin Flaps in the Repair of Scarred or Ulcerative Defect over Bone and Tendon. *Surgery* 1941 9 137

The results and conclusions cited in this article are based upon a series of 9 patients operated upon during a 15 year period for the purpose of correcting chronic ulcerative lesions or deep adherent scars. The majority of lesions were on the extremities.

In selecting the optimum method for coverage of such defects one has to balance the utility of a skin graft against that of a skin flap. Each has certain advantages. A skin graft can usually be placed in one operation, while a skin flap will take at least two operative procedures. A skin graft has about normal thickness and gets its nerve supply quicker than a skin flap, which is often rather thick in appearance. In general, a skin flap has the advantages of a fairly high resistance to infection, some thickness for the purpose of filling a defect, it slightly lengthens an amputated extremity, and it covers a thumb or finger reconstructed by means of a bone graft with subcutaneous tissue. It can be used to cover exposed tendon, nerves, and bones and it retains tissues with sufficient blood supply such a radiation necrosis and sloughs. For the building of a scarless region of thickness for building a part requiring a soft pliable epithelial surfaces and some thickness such as the nose, the cheek, and the lip, and a direct coverage of bone or cartilage the pedicled skin flap has little competition.

It is emphasized that often a skin flap can be transplanted to the opposite leg, ankle, or foot with safety and the resultant aseptic denuded base from which the flap was removed covered by a skin graft at the first operation, which saves time and a considerable number of operations.

In 5 of the 9 cases treated by the authors flaps were used to cover bull-dog feet. Before rotation flaps of the scalp were transferred successfully in one stage. In 27 cases flaps were transferred to the fingers, hand, or arm; the majority were male from the abdomen and were transplanted in two stages. Of these 3 did not hold; 2 failures occurred in small children from whom it was difficult to obtain the needed cooperation. Body flaps were used in 3 cases to cover a ray burn, one of the scrum, one of the groin, lower abdominal and upper thigh, and one over the lower abdominal. Partial sloughing of the flaps occurred in 1 of these cases.

In the cases in which the flaps were applied to the lower extremity the majority of the lesions were due to trauma. In 15 cases the flaps were used. One of these a very useful pedicled flap did not take because of necrosis of the distal end. In 45 of 49 cases leg flaps were used. In only 3 of these was the "take" delayed—a flap was cut off but a second was partially lost. In the latter case the flap was reapplied and a successful result obtained. In 5 other cases there was a partial but not a complete loss.

In a case with a large defect over the ankle and a bulbous foot, pedicled lateral flap was raised after

a relaxing incision was made posteriorly, the skin and subcutaneous tissue brought forward and sutured to the skin and subcutaneous tissue. In only 1 of the 49 cases was the result entirely satisfactory. One wound became infected and a bad partial loss of the flap which required transfer of a flap from the opposite calf.

JOHN J. McDEVITT, M.D.

Patterson, T. C., Keating, C., and Clegg, H. W.: Experiences in the Prophylaxis and Treatment of Clostridial Infection in Casualties from the Invasion of Europe. *Brit J Surg* 1941 33 1

The authors report 16 proved cases of clostridial infection which were treated by local excision of the gangrenous muscle as full a cure as circumstances permit or if no alternative remained, by amputation. The wounds were irrigated freely with a 1% hydrogen peroxide solution to remove the bacteria and lightly dried after which they were covered with a "frost" of sulfathiazole and a percentage of rosin. This irrigation and frosting was repeated twice frequently produced a wound which healed rapidly, often an early secondary suture was possible.

Sulfathiazole was the drug of choice. In the majority of cases a dose of 2 gm. was given, 1 gm. every 4 hours.

Anti gas gangrene serum was also used in 10 cases. The normal procedure was to give 15 to 30 c.c. diluted with equal parts of saline solution, intravenously and to supplement this with 10 c.c. intramuscularly. The dosage was repeated every 6 hours until it was considered that the toxin had been eliminated and the wounds were well on the way to being healed. Each cubic centimeter of the solution contained 4,500 units. The largest dose was 450 c.c.

Penicillin was used prophylactically in 1 case. It was concluded that penicillin could not be depended upon to prevent the development of anaerobic infection. It was used intramuscularly at an initial treatment in 9 cases—15,000 units b.i.d. every 3 hours.

There was 1 death from bronchopneumonia and the anaerobic infection had not been treated. Amputations were performed of 3 arms and 3 legs.

In summary the authors conclude that a real victory is still the keynote of prophylaxis and treatment of gas gangrene. The most useful antibiotic at present are anti gas gangrene serum in combination with sulfathiazole. The place of penicillin in the prophylaxis and treatment of gas gangrene is proved and must remain uncertain until further investigation has been carried out.

LEON J. McDEVITT, M.D.

Cleghill, W. C.: Gas Gangrene Thigh Thwart Cases, with 1 Death. Treated at a Forward General Hospital in Italy. *Lancet*, Lond. 1941 1 1

Clostridial infection was a serious problem in the forward hospitals. The little scene moved from the

the European theater. Heretofore most reports have dealt with cases seen chiefly at the forward casualty clearing stations and the field surgical units level and have shown fatality rates of from 30 to 60 per cent.

The 33 cases reported here were treated at a forward general hospital in Italy and there was but 1 death, which occurred long after the clostridial infection had been controlled. Most of the infections were recognized in from 4 to 5 days after wounding and may have been less fulminating and severe than the previously reported cases, however at least 10 of the cases were fulminating so that some other explanation of the low mortality must be sought. Although ample supplies of penicillin were available, it was not considered justifiable to depend on this drug alone. Full use was made of blood gas gangrene antiserum and sulfonamides.

The diagnosis of gas gangrene is essentially clinical. In general the most reliable signs of clostridial infection were pain or heaviness in a limb, a rising pulse rate with moderate pyrexia, curious mental alertness, icteric tinge of the facies with circumoral pallor, low blood pressure, the characteristic odor and the lifeless appearance of the muscles. Crepitus was not a prominent sign. Its presence is not a reliable guide to the extent of infection in the underlying muscles, for it is ordinarily found in the subcutaneous tissues well in advance of the muscle involvement. The importance of this fact is illustrated by 2 cases in which crepitus could be elicited up to the abdominal wall, and yet it was possible to amputate successfully through the middle or upper thigh.

Cases were classified as of 3 definite clinical types: gas abscess (6 cases), clostridial myositis (17 cases) and fulminating gas gangrene (10 cases).

The sheet anchor of treatment in fulminating gas gangrene is early surgical removal of the source of the toxemia. This usually means amputation in cases in which it is possible, or muscle excision on a large scale. The principle of efficient surgical excision must still be maintained, but experience with penicillin and the sulfonamides encourages the hope that a more conservative approach may be justified in the future. As experience with and confidence in penicillin increased in this series, the approach became less radical, with the result that several limbs were saved. In addition to large amounts of blood and antiserum, the average parenteral dose of penicillin per case was from 300,000 to 500,000 units given at 3 hourly intramuscular injections of 100,000 units. As the outcome is usually determined in from 24 to 72 hours, this will suffice. Most patients were given a course of from 25 to 30 gm. of sulfathiazole.

A very low mortality rate was achieved and the number of amputations (5) was low. Although as a group the cases were of less severity than those seen in forward areas, all the men were extremely ill on admission and the 10 fulminating cases were comparable to those seen in the field surgical units. Penicillin used prophylactically both locally and

parenterally did not prevent the onset of gas gangrene.

Meleney, F. L., Friedman, S. T. and Harvey, H. D.
The Treatment of Progressive Bacterial Synergistic Gangrene with Penicillin. *Surgery* 1945
18: 423

Progressive bacterial synergistic gangrene, due to the associated presence of a microaerophilic non-hemolytic streptococcus and a hemolytic staphylococcus aureus is now accepted as a clinical entity. The authors report 3 cases of this malady that were treated with penicillin.

A patient critically ill with pulmonary abscesses and empyema, failed to respond to sulfadiazine and was treated by resection of a rib and drainage. The typical lesion of progressive bacterial synergistic gangrene developed around the wound in the chest wall. The use of penicillin intramuscularly and intrapleurally resulted in healing of the gangrenous ulcer and cure of the patient.

In a second patient an enterostomy was done following resection of the gangrenous terminal loops of the ileum. Although sulfadiazine was used post-operatively, the patient developed the lesion of progressive bacterial synergistic gangrene around the enterostomy wound. The spreading infection was brought under control by the use of penicillin intravenously and the lesion healed.

In a third case of multiple boils a number of bacterial species including the microaerophilic non-hemolytic streptococcus and the staphylococcus aureus were isolated. In this patient the lesions while they had most of the characteristics of the progressive bacterial synergistic gangrene as described in previous reports, differed in three respects. In the first place they were multiple, second they were not excruciatingly painful, and third the zone of gangrene was relatively narrow. These lesions responded unsatisfactorily to penicillin or to other forms of therapy and the patient died from a pulmonary embolus.

The sulfonamides have not been effective in controlling progressive bacterial synergistic gangrene, but penicillin offers real hope.

Brown, C. W., McClintock, L. A. and Neary, E. R.:
Established Surgical Infections. Treatment with Urea-Sulfanilamide Mixture. *Am J Surg*
1945 70: 4.

The topical use of sulfonamides alone in necrotic or purulent wounds is known to be of little or no therapeutic value. On the other hand, reports of experimental and clinical studies indicate that in the local treatment of grossly infected wounds urea-sulfonamide mixtures possess valuable antibacterial and related therapeutic properties.

The purpose of this investigation is to evaluate the urea-sulfanilamide mixture in the local treatment of established chronic surgical infections. The urea-sulfanilamide which was used was a crystalline mix-

ture consisting of 3 parts of urea and 1 part of sulfanilamide. This specific mixture was selected as most satisfactory on the basis of experimental and clinical observations. The crystalline components in the selected mixture when generously applied to a wound supplied the maximal percentage of relatively insoluble sulfanilamide which would not give rise to foreign-body reaction, and an excess of freely soluble urea sufficient to assure its prolonged action *in situ*.

It was supplied in sealed, resilient, plastic tubes within which the crystalline drugs had been sterilized by a nontoxic, chemical process that does not adversely affect either the urea or sulfonamide crystals. Sixty hospitalized cases of serious—chiefly chronic—surgical infections were studied. They represented most of the usual variety of such infections seen in general hospital practice and consisted of hematogenous and post-traumatic osteomyelitis, purulent and necrotic skin defects that required grafting, pulmonary abscess and thoracic empyema with external sinus tracts, and miscellaneous cases including infected postoperative wounds, trophic ulcers.

In addition, several cases of suppurative peritonitis were studied particularly to determine the rate of absorption of sulfonamide from an infected serosal surface following the topical application of urea-sulfanilamide. In all cases in which the infected wound was external the lesion was dressed once daily and the entire surface area of the wound was freely covered with insufflated urea-sulfanilamide. This required the daily application of from 10 to 20 gm. of the mixture per patient. In cases of draining lung abscess and empyema, from 10 to 30 gm. of urea-sulfanilamide per day were applied locally after insertion of the insufflating container into the fistulous tract. The more devious fistulous tracts were filled daily with the mixture by means of a soft rubber catheter attached to the insufflating container. Intraperitoneally a single dose of from 10 to 20 gm. of urea-sulfanilamide was implanted at the time of operation.

Careful appraisal of a chemotherapeutic agent in surgical infections requires a plan of investigation that considers the many variable factors which may influence the results including among other determining elements the duration, previous treatment, extent of tissue destruction, and bacterial population of each infection.

Frequent studies of the qualitative and quantitative bacterial population of all wounds provided a means of confirming clinical response to treatment with urea-sulfanilamide. Wound cultures were made at the start of treatment and, insofar as possible every three to five days during treatment with the mixture. Specially prepared media which absorbed approximately 0.1 cc. of fluid, were used to obtain samples of wound exudates. From saline suspensions of these aerobic and anaerobic cultures and colony counts were made on meat infusion agar, respect- ively, and on selenite F-thioglycollate agar, respectively.

Cultures on blood agar and in tryptic soy broth were also routine. In addition, serial dilutions of the antibacterial threshold concentration of sulfanilamide for organisms isolated from wounds at the start of treatment helped to evaluate the degree of sulfanilamide-resistance that these bacterial invaders manifested in failing to require an earlier treatment with sulfonamide alone.

Periodic hemopoietic, blood chemistry and pertinent laboratory studies were made in all cases. Clinical progress was charted and recorded in the usual way.

As urea-sulfanilamide comes in contact with a purulent exudate it rapidly goes into solution. As long as the wound discharge is profuse a dry dressing is best used after infiltration of the mixture into the wound. Local edema rapidly subsides as the amount of wound exudate greatly decreases within a few days. At this point it has been advisable to employ dressings soaked in saline solution instead of dry gauze dressings. Saline dressings prevent dryness and crusting of the productive wound and do not impede local absorption of the mixture.

As wound edema subsides it seems that a vascularization occurs and granulation progresses more rapidly than usual. When healthy granulation has appeared and wound discharge is scant, much smaller amounts of insufflated urea-sulfanilamide suffice and do not retard epithelialization as large quantities of the mixture are likely to do at the stage of treatment. In the pregrafting preparation of infected skin defects, however, generous quantities of urea-sulfanilamide may be topically applied up to the time of grafting.

In none of the cases studied has any reaction occurred that could be construed as a reaction of local or systemic toxicity to urea-sulfanilamide. No significantly abnormal findings attributable to the use of the mixture have been demonstrated in frequent hematological and urinary studies throughout treatment.

BERNARD GREEN, M.D.

Ory, E. M., Meads, M., and Finland, M.: Penicillin V. *J. Am. Med. Ass.* 1945 129 157.

Several forms of penicillin have been described as cultures of penicillium notatum. Three of the known penicillins F, G, and V in this country are penicillin 1, 2, and 3 respectively. In Great Britain have been isolated in crystalline form. Commercial penicillins prepared from deep vat cultures contain almost entirely of penicillin G, but those prepared from shallow surface cultures in flasks may contain appreciable amounts of penicillin V ranging from 20 or 25 per cent.

When tested simultaneously with penicillin containing 65 per cent or more of penicillin V and with commercial G is which exhibit almost equal activity. Penicillin G is more active against streptococci, pneumococci and meningococci than penicillin V. It is times more active in penicillin V against strains of pneumococci and meningococci.

viridans were twice as sensitive to penicillin λ and most of the staphylococci were equally sensitive to the two kinds of penicillin.

Levels of penicillin activity in the serum against a strain of hemolytic streptococcus were significantly higher and sustained longer after intramuscular injections of penicillin λ than after injections of the same number of units of regular penicillin.

The methods used both in determining the sensitivity of bacteria and in estimating the serum concentrations are admittedly crude. It is most unlikely however that the consistent differences between the commercial preparations and the lots of penicillin λ observed in the authors' studies could be explained on the basis of such methods. The results obtained with the different lots of penicillin serves to emphasize the superiority of the penicillin λ .

The findings suggest that comparable therapeutic results may be expected with the use of smaller doses or with the same doses given at longer intervals when penicillin λ is used.

A preliminary clinical trial indicated that penicillin λ is nontoxic and at least as effective as regular penicillin in the same doses in cases of pneumonia and probably more effective in gonococcal infections. Further clinical trials with the use of smaller doses and longer intervals are necessary in order to establish the therapeutic superiority of penicillin λ .

JOSEPH K. NARAT, M.D.

Ulrich, H. L., and Dowling, H. F.: Observations on the Continuous Intramuscular Method of Administering Penicillin. *Am. J. M. Sc.*, 1945 310 435.

Use of the constant intramuscular method of penicillin administration in 110 patients is reported and the concentration in the blood of patients studied is compared with that achieved by other methods.

The amount of sodium penicillin required for 12 hours was usually dissolved in 1,000 c.c. of isotonic salt solution and allowed to flow at a constant rate of from 30 to 40 drops per minute into the lateral aspect of the thigh or into the gluteal muscles. When administered at the rate of 200,000 units in 24 hours the concentration of penicillin in the blood remained constant and at therapeutically effective levels 96 per cent of the time whereas with the injection of 25,000 units every three hours similar concentration was obtained only 80 per cent of the time. The corresponding figures for the injection of 20,000 and 15,000 units every 2 hours were 67 and 63 per cent respectively.

No deleterious effects or complications were observed except for mild to moderate pain or discomfort at the site of injection in 6 patients. Pain was usually prevented by changing the location of the needle every 24 to 96 hours. Prompt and complete relief of pain was obtained by the addition of procaine to the penicillin solution. This method

avoids repeated painful intramuscular or intravenous injections, traumatization of the veins and phlebotrombosis. The patient has almost complete freedom of activity.

The authors believe the continuous intramuscular drip to be the method of choice in very ill patients who require continuously high blood concentrations of penicillin.

WALTER H. NADLER, M.D.

Bailey, H.: The Treatment of Cervical Collar-Stud Abscesses with Skin Involvement. *Brit. J. Surg.*, 1945 33 53.

The author describes his experience with 200 cases of tuberculous collar-stud abscesses. Conservative management of these cases consisting of aspiration incision or incision and scraping is considered a pernicious practice. Wide open excision is recommended.

In about 25 per cent of the cases the superficial abscess does not overlie the broken down glands that feed it; indeed the 'factory' and the 'storehouse' may be as much as 6 or 8 inches apart. If success is to attend the method of treatment it is fundamental to remove not only the abscess but also the degenerating glands and the isthmus which connects them.

A proper preoperative clinical examination of the whole neck will unmask the long stemmed collar stud abscess which is the one requiring special consideration.

The standard technique of treatment is as follows:

1. Excision of all unhealthy skin, including skin that at first sight appears healthy but on closer examination is found to be undermined and pathological on its under surface.

2. Complete dissection of relevant diseased lymphatic glands. When the sternomastoid interferes with their clear display the muscle is divided and subsequently reuniting.

3. Hemostasis being rendered as perfect as possible the cavity is sprinkled with sulfanilamide powder and the hole filled with vaseline gauze as it enters the wound, powder is poured on to the gauze, which is never allowed to touch the skin. The vaseline gauze must be of the right consistency; if it is too soft it tends to become displaced and if too dry it sticks to the granulations.

4. The cavity having been packed moderately firmly and filled completely but not to overflowing more sulfanilamide powder is sprinkled on to the surface and a piece of the tulle gras laid over the mouth of the wound so as to overlap its edges.

5. A viscopaste bandage is applied in such a way as to immobilize the neck. Formerly the author used a plaster cast. It is of great importance that the bandage be applied properly so that the patient, often a child, cannot displace it and expose any part of the wound.

The author stresses the fact that all diseased glands must be removed as otherwise a chronic sinus will develop. If during the intervals of repacking the bandage becomes disarranged and the wound becomes exposed secondary infection is likely to occur.

Dressings should be changed every 7 days under absolute aseptic precautions, this should be done by a competent person. In making incisions the surgeon must take Langer's lines into consideration.

In describing the end results the author states that large craters in the neck readily develop clean granulating surfaces and become epithelialized without skin grafting. More often than not the resulting scars are not unsightly and are often linear.

LLOYD J. FROBERT, M.D.

ANESTHESIA

Lundy J. S. Adam, R. C., and Seldon T. H.: Factors Influencing Trends in Anesthesia. *Surgery* 1915 8:1.

At the Mayo Clinic the use of methods of anesthesia in the application of which special personnel is employed (for example, spinal and regional anesthesia that is administered by the professional anesthetist, intravenous anesthesia, intratracheal anesthesia, cyclopropane curare and so forth) has increased from 6.7 per cent in 1912 to 65.4 per cent in 1913. Tribromethyl alcohol as a rectal anesthetic has been more satisfactory than oil and ether by rectum. Barbiturates by rectum plus tribromethyl alcohol still has an apparent advantage over tribromethyl alcohol alone. The use of acetylene was discontinued after 1910 because of the danger of explosion. Since 1917 intravenously administered pentothal sodium has been employed in about a third of the cases in which special methods of anesthesia were used.

The explosion hazard in the use of cyclopropane is well recognized and there have been reports of sudden collapse of patients at the end of long operation, as well as of fibrillation due to the drug. It would appear that if one observes the recommended precautions in the use of cyclopropane it is a wholly useful agent but it is not an essential one except in a limited field, particularly thoracic surgery.

The use of Magill's intratracheal tube has greatly enhanced the value of the inhalation anesthetic agents.

For the last eight years there has been little change in the percentage of employment of the agent used at present.

Barach, A. L., and Rosenstine, E. A.: The Hazard of Anoxia during Nitrous Oxide Anesthesia. *Anesthesiology* 1915 6:412.

The morbidity and mortality following the use of nitrous oxide for surgical anesthesia have increased despite the refinements of administration and the more modern techniques. The safest of all anesthetic agents "used in 1900 has become one of the most if not the most, dangerous one today. Its strongest endorsement has been its lack of toxic reaction and its use in cases of immobility and its lack of discomfort for the patient through its rapid, pleasant induction and emergence. Its single serious imperfection is its lack of potency. In order to fulfill

the requirements of surgical anesthesia in a patient who has not received previous depressant drug medication, the degree of anoxia must be accompanied. Previous reports from other clinics have demonstrated that patients anesthetized by nitrous oxide will always suffer from a severe degree of anoxia. When the percentage of oxygen in the inspired gases is below 13 per cent the arterial oxygen tensions were in the range of extreme hypoxia, 30 mm. of mercury.

The extensive studies of Courville and other research workers have shown that serious as well as fatal results may follow nitrous oxide anesthesia even though it is administered without gross error and by accepted techniques. Examples are given of patients who had died suddenly during anesthesia with nitrous oxide or who had died a few days after the agent was used. Another group of cases was discussed in which recovery occurred but residual mental symptoms indicated cerebral damage of the nervous system. A final group of patients who had transient mental and emotional manifestations but apparently recovered completely. There is essential agreement with Courville's view that such lesions most often include severe and scattered pyramidal nerve cells, patchy necrosis, degeneration of various cortical layers, subcortical degeneration of limited portions of the cortex, and lesions in the lenticular nucleus. It seems probable from Barach's work and others that permanent damage in the frontal lobe cortex as well as in other areas of the brain may take place with little change in personality change although subtle disturbances in emotional response may have been produced. Next to the brain the heart is the organ most sensitive to anoxia. This may be manifested by coronary insufficiency without the warning signs of pectoral pain.

The authors propose the dispensing of cylinders containing 40 per cent nitrous oxide and 60 per cent oxygen to avoid the possibility of anoxia during nitrous oxide administration. Each cylinder should be filled with 150 gallons of the mixture at 2000 pounds per square inch to permit a uniform emergency flow of 10 per cent gas mixture. The authors have argued against the so-called "gas oxygen" cylinders which deliberately expose the patient to severe anoxia, the result of which may be psychomotor paralysis, personalty defect or death from cerebral or respiratory failure. MASON K. M.D.

Mawson, G. M. C., and Deland, E.: Influence of the Liver and Kidney on the Duration of Anesthesia Produced by Barbiturates. *Anesthesiology* 1915 6:453.

The object of the authors was to study the effect of barbiturates by means of partially heparinized and completely rephrenotomized animals. It was whether or not a relationship existed between the duration of action of these compounds and the effect of their detoxification. The patients who were used in the experiment were brought up to date with the

ous references. The method of procedures was described in detail.

Twenty-nine barbituric compounds were studied and the results tabulated in such a manner as to suggest a new classification of the barbiturates according to the site of their detoxification. The index of detoxification was represented as the average duration of anesthesia of control animals is compared with average duration of anesthesia of experimental animals. This index figure was determined for each compound in the partially hepatectomized and the completely nephrectomized animals.

The authors suggested that group 1 contain those barbiturates detoxified mainly in the kidney—barbital and phenobarbital; group 2 contain those barbiturates detoxified mainly in the liver—lithol, amobarbital, oral, alurate, nortal, secobarbital, pentobarbital, and thioethamyl; group 3 contain those barbiturates detoxified approximately equally in the liver and kidney—neonal, delvalinal, phenodorm, and dial; and group 4 those barbiturates possibly detoxified in all the tissues of the body but not to any great extent in the liver or kidneys—pentothal, propyl 1-methylallyl and allyl 1-methylallyl thiobarbiturates.

MARY KARP, M.D.

Robin, P. A. and Collins, V. J. Roentgenological Study of the Male Sacrum As an Aid in Caudal Analgesia. *Anesthesiology* 1945 6 505

Fifty unselected cases were subjected to a preliminary roentgenological examination of the sacrum. Caudal analgesia was then carried out independently and analysis of the results made. The method of x-ray study was described in detail.

A routine anteroposterior view of the sacrum was obtained to determine the apex of the caudal canal and to measure the transverse diameter of the caudal canal hiatus at the level of the 4th sacral segment. Body section roentgenography was used for the lateral view and three or four planigraphic views were made close to the midline to obtain a more accurate delineation of the caudal canal. It was found that the apex of the caudal canal hiatus was situated at the 3rd sacral segment in 46 per cent of the cases and below the 3rd sacral segment in 32 per cent. In 66 per cent of the cases the anteroposterior diameter was between 2 and 5 mm. In 50 per cent it measured between 3 and 4 mm. and in 18 per cent it measured less than 2 mm. There was found to be a direct correlation between these findings and the ease with which the canal was entered. In 6 cases or 12 per cent, no hiatus was apparent on the film, and it was believed a complete bony block of the opening of the caudal canal existed. Variation in size of the intertuberosity diameter was not marked or significant. In 6 per cent of the cases no opening of the caudal canal was revealed on the anteroposterior films. This differed from the results as viewed on the lateral planigraphic films, but was explained by the lack of depth of the hiatus and the possible distortion of the film.

In 10 per cent of the cases small apertures were seen in the posterior wall of the caudal canal. In 14 per cent the cornua were flat or absent. A completely blocked lumen of the canal at the opening was noted in 10 per cent and a partial block either at the opening or above was observed in 14 per cent of the cases. The sacrum appeared to deviate from the midline in 6 per cent of the cases and there was an exaggerated sacral curve in 16 per cent.

When observations were made on the patients after caudal anesthesia was attempted, it was found that 8 cases, or 16 per cent, were unsuccessful cases because of the inability to introduce the needle into the caudal canal. Most of these cases had roentgenographic findings that showed a complete block of the lumen or an absence of the lumen.

A method of x-ray study of the sacrum with special reference to the caudal canal was thus presented. The studies indicated the importance of preliminary roentgenological investigation prior to the attempt to produce caudal analgesia. The significant anatomical findings contributing to unsuccessful analgesia were a narrowed anteroposterior diameter, absence of the hiatus, a blocked lumen and angulations of the posterior wall of the caudal canal.

MARY KARP, M.D.

Newton, C. W., Jr. and Andros, G. J. Continuous Caudal Analgesia in Curettage for Abortion. *Am. J. Obst.*, 1945 50 430

In an attempt to decrease the blood loss at the time of therapeutic abortion and curettage for incomplete abortion, the authors have used continuous caudal analgesia as an anesthetic method. This technique maintains tonicity of the uterine muscle and at the same time provides analgesia of the perineum, vagina, and of the cervical and fundal portions of the uterus.

In 22 consecutive cases the average blood loss was less than 40 c.c. per patient, varying from less than 5 c.c. to 125 c.c. Seventeen of the patients lost 50 c.c. or less. There were no anesthetic, operative, or postoperative complications. Postoperative convalescence and return to normal activity of the patient is hastened.

EDWARD L. CORWELL, M.D.

Roman, Vega, D. A., and Adriani, J. The Efficiency of "Oenethyl" (2 Methyl Amino-Heptane) As a Vasopressor Substance for Spinal Anesthesia. *Saudi. J. J.* 1945 38 635

Because aliphatic amines have never been employed for overcoming the hypotension of spinal anesthesia, the authors have been interested in determining the clinical value of such a compound for this purpose. This report comprises experiments with "Oenethyl" in 700 surgical patients with a preliminary report on the first 100 patients. 2 Methyl amino-heptane, or Oenethyl, is a clear volatile liquid which is slightly soluble in water and mildly alkaline. Its vasopressor action is similar to but more sustained than that of epinephrine. It produces a rise in both systolic and diastolic pressure

and an increase in pulse pressure with improvement in heart action, dilatation of the pupils, piloerection, a bronchodilatory action, decrease in renal volume and some stimulation of respiration, but no action on the smooth muscle of the uterus. Its pressor effect is due largely to constriction of the arterioles. Its toxicity is low and it does not appear to have any direct stimulating or depressing action upon the central nervous system. Large doses may cause weakness, lethargy, drowsiness, or prostration, and toxicity is manifested by hypotension and depression of the pulse rate.

Fifty-three per cent of the cases studied received *orphenethyl* prophylactically to avoid anticipated hypotension. In the rest of the cases the drug was given therapeutically to combat hypotension when it appeared. The drug was administered intramuscularly or intravenously, the latter route being chosen when an acute hypotension occurred. The drug appeared to be an effective vasopressor which successfully combated the hypotension of spinal anesthesia in the majority of the patients to whom it was administered. In 3 per cent of the cases it failed to restore the blood pressure to the preoperative level. However, in no case did it fail to cause some elevation.

From 5 to 100 mgm. of the drug were found to be the therapeutic dose for intramuscular injection. When used intravenously the effective dose varied

from 10 to 50 mgm. and the best results were obtained by administering the drug slowly in small doses of 10 mgm. each and allowing one-half hour to lapse between the administration of each fraction. Overdose caused an excessive rise in the blood pressure and a temporary disturbance in cardiac rhythm.

Venopressor studies on 6 subjects showed a lowering of pressure to preanesthetic levels. There was no significant alteration in pulse rate. Tachycardia was not observed at any time. Fifteen per cent of the patients demonstrated pupillary dilatation which persisted for approximately 30 minutes. Transient dizziness was found in about 25 per cent of the cases and nausea and emesis in 5 per cent. The onset of the pressor effects occurred in about 2 minutes after the drug was administered intravenously and from 3 to 5 minutes when it was given intramuscularly and as a rule the effect was maximal 10 minutes and was sustained for the duration of the operation following a single injection.

In 25 patients the drug was a (musclemen) and ephedrine sulfate had failed to restore the blood pressure to satisfactory levels and in all of these cases the blood pressure rose satisfactorily.

The authors concluded that "*orphenethyl*" is to be a satisfactory vasopressor for spinal anesthesia and recommended its further clinical trial.

BY KAY M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Krause, G. R.: The Roentgen Diagnosis of Pulmonary Infarcts. *Radiology* 1945 45 107

Roentgenologically a pulmonary infarct may mimic any other lung disease and be interpreted in correctly more often than any other pulmonary lesion. This may be due to its supposed rarity.

The author reviewed 344 cases of lung infarct which were seen at autopsy. The infarct was the direct cause or major contributory cause of death in 174 cases and in only 22 per cent of that number was it diagnosed correctly. In 73 cases clinical and roentgenological correlation with postmortem findings was adequate.

The literature reviews many positive roentgen findings of pulmonary infarct. Wharton and Pearson (1922) described clouding in the costophrenic angle as an early sign of infarct. Wessler and Jaches (1923) described the triangular shadow with the base toward the axilla. Smith (1938) described 6 signs of infarct: hazy, horizontal, clouding at the base, the suggestion of pleural effusion, increased circular density with cavity formation, dense linear shadow and basal collapse of a lobe. Westermarck (1938) described the area of avascularity in the region of the embolus. Jellen (1939) stated that an infarct may not be apparent for several days following the embolic process.

The majority of infarcts occur in cardiac and postoperative patients. Clinical findings of pulmonary infarct are sudden, sharp pleural pain and dyspnea, moderate elevation of the temperature and white blood count, with a gradual return to normal within a few days if the patient survives. Chilling is almost never present. The physical findings are rales, change in breath sounds and friction rub.

Most infarcts occur in the right lower lobe; they are frequently multiple and their average size is from 2 to 6 cm. The shape of the infarct tends to follow the lung contour and is not characteristic. Superimposition of infarcts may also cause a variation of the shape.

Complications of pulmonary infarct are secondary bronchopneumonia, pleural effusion, lung abscess and pulmonary pleural fistula. These complications obscure the detail and make the interpretation much more difficult.

Healing of infarcts does not occur by resolution. The necrotic tissue is replaced by fibrous tissue which results in scar formation and may be stellate or linear in type.

Infarcts must be differentiated from lobar pneumonia, bronchopneumonia, atypical pneumonia, tumors, passive hyperemia, pleural effusion, cysts and plaques of atelectasis.

In lobar pneumonia the pulmonary involvement is greater than that in the presence of an infarct.

Within a 24 to 48-hour period it may spread rapidly in spite of good clinical response to chemotherapy. In bronchopneumonia the involvement in the bases is multiple patchy and mottled. Atypical pneumonia resembles bronchopneumonia. Primary pulmonary tumors with resultant collapse of the lung can best be demonstrated by overexposed Bucky films. Passive hyperemia causes a dense bilateral linear shadow in the hilum radiating to the periphery with a gradual fading. Pleural effusion may be either free or encapsulated. Free fluid occurs in the lower lateral portion of the lung field with a smooth curved upper border and a convexity inferior. The superior border of an infarct in this area is straight with a convexity upward. Infarcts are never elliptical as in interlobar effusions. Air filled or fluid level cysts present no diagnostic difficulty; however cysts filled with fluid do. These rarely occur against a pleural surface and are almost spherical in shape. Plaque or disk atelectasis may be difficult to distinguish from an early infarct. However within a few hours the picture will have changed so that a diagnosis of atelectasis may be eliminated or confirmed. All infarcts leave scars and reach the pleural surface at some point; they may be multiple, are found at different planes and are shorter than atelectatic plates.

Since pulmonary infarcts may mimic any other lung lesion it is essential to analyze the roentgen and clinical data carefully for the welfare of the patient. If this is done, an accurate diagnosis of pulmonary infarct will be expedited with prompt institution of adequate therapy. MAURICE D. SACHS, M.D.

Thomas, S. F.: The Value of Gastric Pneumography in Roentgen Diagnosis. *Radiology* 1945 45 128

Although the importance of gastric pneumography localizing a mass in the body or tail of the pancreas has been stressed by previous writers to date very little attention has been paid to this useful procedure as a means of localizing tumors in the upper abdomen.

For the purpose of distending the stomach the author modified the original technique of Engel and Lysholm by using a small calibered stomach tube instead of effervescent powders. The quantity of air injected varied from 300 to 800 c.c. The patient lies prone with high supports under the pelvis and chest. The x-ray beam is horizontal and a vertical Bucky diaphragm is used.

The normal retrogastric space is equal to the depth of the first or second lumbar vertebra. Caution must be exercised in removing all fluid and food contents from the stomach prior to the installations of air or diagnostic errors may ensue. Aside from pancreatic pathology the retrogastric space may be increased by obesity, ascites, liver tumors, meta-

treated patients, 30 per cent were symptom free one year after therapy.

The authors emphasize that an early diagnosis and prompt orthopedic and x ray therapy will yield the best results.

MISCELLANEOUS

Jollis, B.: The Causes and Prevention of Radiotherapeutic Edema of the Larynx. *Brit J Radiol.*, 1945 18 378.

The author correlates the available data which have an influence on the complex problems of edema of the larynx and draws certain conclusions as regards preventive or therapeutic measures.

Physiopathology. There are multiple factors upsetting the normal equilibrium between tissue spaces and the bloodstream such as (a) permeability of the membranes (b) osmotic and diffuse potentials (c) lymphatic and venous obstruction and (d) organ activity as for example edema surrounding the salivary glands. The last is of particular interest when the edema occurs in the neck undergoing radiation treatment. Other factors are (1) infection (leucotoxine), (2) predisposing factors as plethoric hydremia (3) milieu interieur in which the acids resulting from a breaking down of inflammatory or neoplastic tissue lead to the production of edema. (4) sensory nerves and sympathetic local anesthesia which prevents or diminishes edema. (5) hormones adrenalin-decreasing permeability and acidification, and (6) decreased extravascular pressure.

Anatomy. The term edema of the glottis is a misnomer since most of the edema occurs in the aryepiglottic folds. Weintraub who made an extensive study of the connective tissues of the neck describes—apart from the ordinary subcutaneous connective tissue—3 varieties of connective structures: (1) a membranous periorganism of lamellar sheetlike connective tissue, which forms the adventitial covering of various organs and structures, (2) areolar or shearing connective tissues which form the anatomic or surgical spaces and lie between moving parts and (3) nerve-vessel carrying tissues which are intermediate in their physical consistency between the areolar and membranous varieties.

The second variety plays the most important role in edema of the neck.

Radiobiology. There is always a lag between the irradiation and the first biochemical and histological changes corresponding to the clinical latent period. The variations of ions in the blood of irradiated persons and their effect on edema are shown in Table I.

The many other factors which may influence the edema as the result of irradiation are grouped schematically in Table II.

Treatment of edema. As may be seen a rather gloomy picture is obtained in regard to the chances of treatment of radiotherapeutic edema. Nevertheless certain measures may prove of clinical benefit. A mixed diet with adequate protein content is essential. Histaminase and vitamin C should be tried.

TABLE I.—VARIATIONS OF IONS IN THE BLOOD IN IRRADIATED PERSONS

X-ray transmembranalization	Edema favoring and preventing factors
Cations	
N increased	N edema favoring factor
K increased	K edema favoring factor
Ca decreased	Ca edema preventing factor
Anions	
Phosphate increased	Phosphate edema preventing factor
Bicarbonate decreased	Bicarbonate edema preventing factor
Cl decreased	Cl edema favoring factor
Decrease in anions—more acid values	(N Cl edema favoring factor) as transitory effect

Foci of infection should be attended to. Alkaline gargles (collintorium phenolis alkalinum) seem advantageous in conjunction with alkaline mixtures per os and 10 per cent calcium gluconate given intravenously. For the combating of pain spraying of the throat every 4 hours with a solution of urethane 1:6 in water with 1 per cent ephedrine, 1 per cent cocaine and a few drops of peppermint is recommended.

TABLE II.—OTHER FACTORS WHICH MAY INFLUENCE THE EDEMA AS THE RESULT OF IRRADIATION

Edema producing factors	How affected by growth	How affected by X-rays
Damage to vessel wall	F	F F edema
Capillary dilatation	F?	F favoring
Ascoria	F	F factor present
Increased hydrostatic pressure (passive)	F	F
Adrenella deficiency	F	F
Infection	F	—
Inflammation	F	F
Pain (via sympathetic)	F	F
Lymphatics	F	F
Venous obstruction	F	F?
Organ activity (general)	F	F
Organ activity (specific)	F	F
Extravascular pressure	—	F
Scurrag	—	F
Predisposing regional factors	F	F
Diffusion potentials	F	F
Metabolites	—	F
pH	F	F
Endocrine	F	F
Irradiation	F	F
Histamines	F	F

mended. Some patients object to the bitter taste of the spray but all of them agree that they feel much better with the spraying than without it.

Lawson, F. E.: Gall Bladder Dye (Iodophthalein Sodium); Effect of Intravenous Injections on the Coronary Flow, Blood Pressure, and Blood Coagulation. *Arch. Int. M.*, 1945, 76: 43.

The dangers of intravenous cholecystography have been cited in the literature since 1915. A review of this literature by the author reveals that most of the patients sustained coronary arterial occlusion. One case of syncope with loss of the feces and urine was reported. Consequently cardiovascular disease was regarded as the chief contraindication.

The author adds his experience with 4 cases. Two of these are classed as anaphylactic shock mainly because the fall of the blood pressure responded to epinephrine and to conventional shock therapy. One of the patients complained of substernal pain, which was not relieved by theophylline ethylenediamine but serial electrocardiograms were negative.

The other 2 accidents are considered by the author as having been caused by coronary occlusion. Both patients showed electrocardiographic changes compatible with or indicating myocardial infarct. One patient died 24 days after the administration of the gall bladder dye (which in this case was given orally in contradistinction to the other cases). Both patients were known to have suffered from angina pectoris.

The following experiments were made in connection with this problem.

1. Measurement and kymographic registration of the coronary blood flow with the Morawitz cannula and of the carotid arterial pressure in 4 dogs, before, during, and after the intravascular injection of gall bladder dye. The dose was proportionate to that given to human adults. The injection caused a fall of the blood pressure and an increase of the coronary flow in all of the cases.

2. Determination of the influence of the gall bladder dye (iodophthalein sodium) on the coagulability of the blood of 7 human subjects by means of the De Takáts heparin tolerance test. In 4 cases the coagulation time was increased and in 3 cases it was decreased. The blood pressure dropped in 5 patients and remained unchanged in 2.

The author draws the following conclusions:

1. Iodophthalein sodium produces an increase in the coronary blood flow in dogs.

2. It causes the blood pressure to drop in human beings and in dogs.

3. The fall in blood pressure may explain the mechanism of shock which the author had occasion to observe twice.

4. The mechanism causing coronary arterial occlusion is not clear.

5. The intravenous injection of iodophthalein sodium is contraindicated in persons with coronary arteriosclerosis (if for no other known reason than the drop in blood pressure it causes).

MISCELLANEOUS

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Vinnard R. T.: Three Hundred and Fifty Two Cases of Tetanus. *Surgery* 1945 18 482.

Among 352 patients with tetanus treated from November 1 1934 to October 31 1944 the total mortality was 45 per cent excluding the deaths which occurred in the first 36 hours the net mortality was 34 per cent. In the past 3 years the mortality rate was substantially reduced (a total mortality of 31 per cent and a net mortality of 18 per cent). Routine immunization by means of tetanus toxoid among the population of tetanus-prevalent areas as effectively practiced by the Armed Services in World War II is highly desirable.

Reduction in the mortality rate would also be furthered by the following procedures: 1. Routine administration of prophylactic antiserum (preferably 3,000 or more units) in the treatment of all injuries to patients who have not previously received toxoid immunization. 2. Education of lay people to report early and of doctors to recognize and institute immediate therapy for symptoms of early tetanus. 3. Immediate intravenous administration of adequate amounts of antiserum. 4. Complete excision or debridement of all possible foci of infection including umbilicectomy in cases of tetanus neonatorum. 5. Adequate sedation. 6. Therapeutic doses of sulfonamides to prevent secondary infection and as prophylaxis against pneumonia. 7. Daily intramuscular administration of from 40,000 to 50,000 units of antiserum to all patients in whom the original foci of infection cannot be found or be completely removed. 8. Good nursing care. 9. Adequate caloric and fluid intake by means of stomach tube feedings. WALTER H. NADLER, M.D.

MacFarlane, R. G., and MacLennan, J. D.: The Toxemia of Gas Gangrene. *Lancet*, Lond. 1945 249 318.

The clinical features of toxemia in gas gangrene have been described. A "collagenase" has been identified in clostridium welchii toxin and its significance in gas gangrene discussed. The possibility that the general toxemia of gas gangrene is not due to alpha toxin but to the products of tissue breakdown has again been studied, particularly in animals. Some evidence in favor of this theory has been obtained. A possible relationship between the toxemia of gas gangrene and that seen in other forms of shock has been noted.

MacLennan, J. D., and MacFarlane, R. G.: Toxin and Antitoxin Studies of Gas Gangrene in Man. *Lancet* Lond. 1945 249 301.

By the lecitinase reaction it is possible to make sufficiently reliable titrations of alpha toxin of

clostridium welchii and its corresponding antitoxin for observations in the field.

As diagnostic procedures in early gas gangrene neither the lecitinase nor the hyaluronidase test has proved satisfactory.

In 4 of 27 cases of gas gangrene—almost all of them caused by clostridium welchii—free alpha toxin was detected. In only 1 instance, however, was a positive reaction obtained with material taken during life. WALTER H. NADLER, M.D.

Hall, I. C.: The Occurrence of Bacillus histolyticus in Accidental Wounds without Recognized Specific Infection. *Surgery* 1945 18 369.

The comparatively infrequent demonstration of bacillus histolyticus in accidental wounds probably gives an erroneous conception of the true frequency of its occurrence. This bacillus is easily overlooked in a bacteriological examination of a mixed infection. On media the organism grows in minute colonies that are likely to be overlooked in a mixed culture by all but the best trained and most meticulous bacteriologists. This accounts for the fact that, although widespread in nature, the bacillus histolyticus was not discovered until 1916.

Pure infections with this organism are rare. The typical lesions produced by pure infections of bacillus histolyticus are most often masked in cases with mixed infections and therefore not recognized.

The bacillus histolyticus was demonstrated in cultures taken from the debrided tissues in 17 civil wounds. There were 7 compound fractures, 5 lacerations, 3 gunshot wounds and 2 burns. This was believed to be the first time that this organism was demonstrated in burns. DAVID H. LYNN, M.D.

Willett, F. M. and Weiss, A.: Coccidioidomycosis in Southern California: Report of a New Endemic Area with a Review of 100 Cases. *Ann Int Med.* 1945 23 349.

A new and rather large endemic area of coccidioidomycosis is reported with this review of 100 cases. The region is roughly triangular bounded by Banning and Needles, California, and Yuma, Arizona. Following admission of a number of cases of the disease to the March Field Station Hospital repeated skin tests were made on 573 soldiers representing both white and colored troops who were performing a dusty type of work at the edge of the desert. In 135 men a "change over" from negative to positive skin reaction was found. Of these men 83 were hospitalized with acute pulmonary coccidioidomycosis. The remaining 52 had insufficient findings to warrant hospitalization and were eventually classified in the clinically inapparent group. These findings established the fact that a considerable part of this desert area was endemic for coccidioidomycosis.

The cases reported here presented no diagnostic problem, since 83 were found as a result of the epidemiological survey and 17 additional cases came from the desert area. The history shows residence assignment, travel, or recent activity in a known or suspected area. A suggestive history in the presence of a pulmonary ailment requires consideration of coccidioidomycosis in the differential diagnosis. By far the greater number of initial infections with coccidioidomycosis are of the inapparent or asymptomatic type. In decreasing order of frequency the symptoms occurring in 100 cases of pulmonary coccidioidomycosis were fever, chest pain, cough, malaise, anorexia, headache, pharyngitis, chills, cutaneous manifestations, joint pain, conjunctivitis, and hemoptysis. Physical examination is only moderately helpful in the diagnosis. Most of the patients are obviously suffering from a respiratory infection without specific physical findings. Unless there are skin or joint manifestations, the physical signs are not revealing. Roentgenograms are of great help both in the diagnosis and in following the course of the disease. The roentgenological findings may be roughly divided into the following categories: (1) varying degrees of parenchymal infiltration, (2) hilar adenopathy and thickening, (3) fluid, (4) nodule densities, (5) cavitation and (6) bone lesions.

The skin test is probably the most helpful single test when used in conjunction with other aids, i.e., travel history, roentgenograms, sedimentation rate, differential blood count, and serological studies. Failure to react to coccidioidin used as an intradermal skin test in a concentration of 1:100, rules out the possibility of coccidioidomycosis provided sufficient time has elapsed to permit the individual to develop the necessary sensitivity except in those patients with disseminated infections. Serological studies were of inestimable value both in making a definite diagnosis and in following the course of the disease. Dissemination was predicted before it occurred in every case by serological tests on the basis of high titers in complement fixation. This was not based on the reaction to the skin test which in 1 instance of dissemination was completely negative. The declining antibody titer was used as an index of safety in mobilization of the patient. The differential and total leucocyte count was of interest mainly because of the eosinophilia, which varied between 5 and 18 per cent of the total leucocyte count. The erythrocyte sedimentation rate was of considerable value, being increased in all patients and varying between 16 mm./hr. and 46 mm./hr. This test was useful both in diagnosis and prognosis. The impression was obtained that sputum examination in the diagnosis of coccidioidomycosis is not an entirely satisfactory method of diagnosis.

Cavitation and dissemination are the two main complications of the disease. The latter is of far greater importance than the former although probably less frequent. In 3 cases of cavity in white sol-

idiers one cavity closed and the other showed a strong tendency toward closure, while in 4 cases of cavity in negroes only 1 cavity closed. Despite the conservative treatment accorded the patients in this series, dissemination occurred in 4 patients, all of whom were colored soldiers with complete bed rest. One of the cases terminated fatally with a generalized miliary dissemination.

The average case of acute pulmonary coccidioidomycosis has an extremely good prognosis for complete recovery. Barring dissemination or complicating cavitation, the average case is almost in the class of a self-limited disease when given proper treatment. The main essential of treatment is adequate bed rest, and until the condition is markedly improved the should be absolute bed rest. The criteria for return to duty were based on the clinical findings, roentgenograms, sedimentation rates, serological studies and absence of evidence of dissemination. Illustrative cases are presented.

JOHN L. LAMBERT, M.D.

Ory, E. M., Meads, M., Brown, B., Wilson, C., and Finland, M.: Penicillin Levels in Serum and in Some Body Fluids during Systemic and Local Therapy. *J. Lab. Clin. M.* 94:30-34.

The rational choice of dosage and route of administration of penicillin presupposes some acquaintance with the effective concentrations of the antibiotic which can be attained and maintained at the site of the infection by the different methods. The desired concentration in any given case will depend, of course, on the susceptibility of the infecting organism. This communication deals with the concentrations of penicillin obtained in serum and in certain body fluids of adult medical patients after the administration of various doses of commercial penicillin by different routes. The data were obtained almost entirely on patients while they were under treatment. The method used is subject to considerable error, but it is adequate for these purposes since it was not intended here to offer any accurate measures of the absorption and fate of penicillin in the body.

The concentrations of penicillin which destroy the common bacteria encountered in medical infections were studied by the authors by a very standard method so that the results are comparable. They indicate that the smallest concentration of penicillin which was measured in the present study, namely 0.03 unit per cubic centimeter, is adequate to sterilize actively growing cultures of almost all strains of the gonococcus group A hemolytic streptococcus, about half of the strains of the meningococcus, and a somewhat smaller proportion of the strains of the pathogenic staphylococci. Undoubtedly the accessibility of the penicillin to the organism and many other factors, most of which are still unknown, come into play and account for some of the discrepancies between the *in vitro* and *in vivo* results.

The serum levels of penicillin obtained after various doses and intervals during systemic administration indicate that for any given dosage only a

MISCELLANEOUS

of levels rather than any specific values can be obtained. In general, higher levels are attained and maintained with the larger and more frequent doses. Levels are not directly proportional to the amount given in the dose except possibly in any given individual under constant intravenous therapy. The results in patients with cardiac or renal insufficiency indicate that the volume of urinary output and the rate of the kidney function may materially affect the height and persistence of penicillin levels after a given dose. Such patients usually attain and maintain any given level with appreciably smaller doses given at longer intervals than do persons with normal renal function and those who excrete larger volumes of urine.

The problem of whether or not topical injections are necessary in cases of meningitis, infection of the serous cavities, or walled-off focal abscesses will be answered more directly on the basis of clinical results than by any analysis of data such as those given in this article. The present observations and similar studies by others indicate that there is some diffusion into all serous cavities but that this is erratic and usually only slight. Clinically, it is already recognized that these infections after they have been established do not often respond to systemic treatment alone in spite of the fact that bacteriostatic concentrations for the offending organisms can often be demonstrated in the exudate.

In cases of meningitis there are differences expressed in the literature, both as to the penetration of penicillin into the cerebrospinal fluid and as to the necessity for having such penetration. Small amounts of penicillin have been found by others in individual cases particularly after massive systemic doses. This has not been the authors' experience nor that of others who have used larger doses in a greater number of cases. Some cases of bacterial meningitis have been reported as cured without resort to intrathecal injections of penicillin but these cases are not entirely convincing since few if any of the patients had received systemic penicillin as the only specific therapy. On the other hand the experience in the authors' clinic and in many other clinics indicates that not only is intraspinal therapy necessary but in some instances it is necessary to resort to injections into the cerebral subarachnoid space or even into the ventricle for complete recovery.

The necessity for systemic treatment when penicillin injections are given into infected body cavities will depend on the circumstances in each case. Some absorption takes place from all the cavities, but this is too erratic and therefore the effective levels are sustained in the circulation for variable periods. Some workers have found the poorest absorption from thick walled cavities and from abscesses which are walled off. Obviously therefore if there is evidence of infection of tissues away from the infected cavity into which the penicillin is being injected systemic treatment is definitely indicated. The absorption from the cavity may however be adequate

to protect against spread of the infection from the site of the injection as a result of the procedure. It is possible that diffusion out of cavities is given at the same time and that may be a reason for using it. Evidence for this, however, is scant.

BENJAMIN GOLDMAN, M.D.

DUCTLESS GLANDS

King, B. T., and Rosellini, L. J. The Treatment of Acute Thyroiditis with Thioracil. *J. Am. Med. Ass.*, 1945 129 267

A series of 11 cases of acute thyroiditis is reported in which cure was effected in 8 by the administration of thioracil. Initially the drug was tried experimentally on a woman who complained of increased nervousness and irritability and who was found to have an acutely swollen and tender thyroid gland, a temperature of 99.6 and an elevation of the white blood count. After receiving 0.2 gm of thioracil t.i.d. for 7 days she was well and free of symptoms, although the thyroid gland remained enlarged and indurated. Continuation of therapy with dosages of 0.2 gm of the drug daily for two weeks resulted in return of the gland to normal size and consistency. The patient was subsequently observed for 4 months with no change in her condition.

Although penicillin has not been employed other methods have proved ineffectual in the treatment of acute thyroiditis. Iodine, rest, hot applications, ice bags, and sulfonamides were of no value. Although x-ray radiation was found definitely to shorten the duration of the disease varying degrees of hypothyroidism and myxedema have resulted from this procedure in a discouraging number of cases. Bacterial cultures of diseased thyroid tissue removed by surgery have never been positive, but it was intimated that the possibility of virus etiology of this condition deserved investigation with possible bearing on the mode of action of thioracil.

Cases for the series were carefully selected 7 cases of acute thyroiditis being included with 3 cases of migrating thyroiditis (the acute process beginning in one part of the gland and spreading to the rest) and 1 case of Hashimoto's struma. Cases of toxic goiter and 1 case of Hashimoto's struma and goiter suppurative thyroiditis, Riedel's struma and longstanding colloid and adenomatous goiter were not included. The diagnosis of acute thyroiditis a clinical rather than a pathological one was made on the basis of enlargement, tenderness and firmness of the all or part of the thyroid gland together with the clinical findings mentioned in the previous case history.

In the 8 cases cured the treatment was continued for 3 weeks or less. All of the patients were symptom free in one week, and in all the glandular enlargement and tenderness disappeared. In 1 case treatment had to be terminated before the 3 weeks were up because of intolerance to the drug, but nevertheless this case was included in the group of cures. In 2 of the 3 other cases treated with thioracil the

Fig. 2. Details of the end-to-end suture of the divided aorta. 1. The aorta is temporarily rotated so that the back wall can be stitched first. 2. The back wall is sutured with a continuous, everting stitch that includes the full thickness of the aortic wall. 3. The aorta is allowed to rotate back

into normal position, the back wall suture being complete. 4. The stitch is carried around onto the front wall. 5. The anastomosis is complete, the edges of the aorta are everted. 6. A cross section shows that the intima of the upper and lower segments are in contact with each other.

luminal clotting at the site did not prove to be a serious factor with the method of suture illustrated. A serious complication of these operations was hind quarter paralysis. Studies of this complication were made by occluding the aorta in 20 dogs for varying periods of time, and it was found that paralysis did not develop when the aorta was obstructed for less than 10 minutes.

Two human patients have been operated upon for coarctation of the aorta. One of them survived, the other died with an uncontrollable dilatation of the heart following removal of the clamps. This emphasizes the importance of slow removal of the aortic clamps.

It is concluded that it is technically feasible to remove a narrowed portion of the aorta in man.

to re-establish aortic continuity by the method described

Grimm, P. D., and Martos, V. F.: Studies in Oleothorax. The Bacteriostatic Action of Oils on the Tubercle Bacillus. *J. Thorac. Surg.* 1945 14 265

Several of the unsaturated fatty acids have been reported to be bactericidal for the tubercle bacillus. In this experimental study the authors found that cod liver oil and peanut oil have no effect on the virulence of the tubercle bacillus.

The difference between these results and those of other investigators may be due to a marked difference in the resistance of the bacterial strains used (by the other workers and the authors) to cod liver oil, or to a difference in the oils employed. It is possible that the oils available today are more highly purified than those of a decade ago, and have been freed from the substances responsible for the bacteriolytic action.

Casein was included in this study because it has been used extensively in disinfection oleothorax. Cod liver oil and peanut oil were studied because of the reports of their inhibitory effect on the tubercle bacillus. The authors concur that these oils have an inhibitory action on the growth of the tubercle bacillus. However the subsequent growth of the organisms on a rich medium and their normal virulence when injected into guinea pigs indicate that the oils adherent to the tubercle bacilli inhibit their growth by a physical rather than by a chemical action.

Grimm, P. D., and Westra, J. J.: Studies in Oleothorax. The Use of Oils in Disinfectant Oleothorax and in the Re-expansion of the Lung in Tuberculous Empyema (Preliminary Report) *J. Thorac. Surg.* 1945 14 270.

Oleothorax with peanut oil and cod liver oil has definitely established its value in controlling tuberculous infection of the pleura. Further treatment of the empyema space is determined by the condition of the lung. The authors have found that an oleothorax of irritant oils produces an obliterative pleuritis and seals over the subpleural foci of infection. If the visceral pleura is not too thick and the lung shows a tendency to re-expand, an uncontaminated infection in the lung can be given priority and the oleothorax continued. When the parenchymal lesion is sealed, the lung may be allowed to re-expand. The lung gradually re-expands if assisted by the periodic removal of oil and air if they are present, and by the maintenance of negative intrapleural pressures. If the lung does not re-expand entirely a less extensive thoracoplasty than would otherwise be necessary can be performed. Thus early use of irritant oils may obviate the mutilating Schede procedure.

In the conduct of oleothorax, frequent examination of the patient with periodic removal of pus or fluid, and maintenance of negative intrapleural

pressures, is mandatory. This avoids empyema or escape of oil through a needle opening and diminishes the chances for the formation of a bronchial fistula. There is great individual variation in the rate of fluid or pus formation, and disappearance of the tubercle bacilli. Oil and a little fluid, with or without bacilli, can be present in the chest for an indefinite period without clinical symptoms. One patient with diabetes, a very poor surgical risk who had a tuberculous empyema, carried cod liver and pus in the pleural space for 6 years before a bronchial fistula developed. This patient failed to report for aspirations during this time and increased tension helped to cause the fistula.

With oleothorax, the surgical problems of aspiration are diminished and closed drainage with empyema tubes and catheters is eliminated. The authors have always considered open drainage contraindicated unless a bronchial or pleural fistula is present. Of 50 patients with varying degrees of purulent effusion and empyema, 6 experienced re-expansion of the lungs without reactivation of the pulmonary infection or further plastic operation for closure of the pleural space. Of the remaining 14 patients 10 now have oleothoraces which are negative for tubercle bacilli. Re-expansion of a lung may be lifesaving to the patient if a tuberculous infection develops or is present in the other lung as it was in 11 cases of this series. The use of irritant oils in oleothorax adds a reversible procedure to the treatment of tuberculous empyema, which heretofore has often demanded an irreversible one.

Zerbin, E. D.: The Importance of Ascorbic Acid (Vitamin C) in Chest Surgery *J. Thorac. Surg.* 1945 14 309.

The closure of the bronchi after partial or total resection of the lung and the gastroesophageal anastomosis still constitute two important problems in thoracic surgery. Defective cicatrization frequently occurs in both cases and results in a bronchial or esophageal fistula. The surgical technique employed in the procedure is very important in the prophylaxis of these complications and in obtaining a good scar, but the technique constitutes only one of the factors influencing scar formation. In many cases it is impossible to obtain a good suturing because of local conditions, but even with the best technique the disruption of the sutures from lack of scar formation, may occur.

The amount of ascorbic acid in the blood and in the tissues has been considered one of the most important factors in the formation of the intercellular collagenous tissue and in the strength of the scar both in animals and in human beings. The amount of ascorbic acid in some patients was studied by the author before and after lobectomy, pneumonectomy, and esophageal resection. The blood proteins of these patients were tested continuously because hypoproteinemia is another important factor in scar formation which should always be corrected.

The chest condition which brings the patient to the hospital may be responsible for a low plasma ascorbic acid level before the operation. In 22 patients examined the average level found just after admission was 0.15 mgm. per cent of plasma ascorbic acid (normal considered between 0.8 to 1.2). Only 1 patient had a normal blood level before operation and 9 patients showed complete absence of ascorbic acid in the plasma.

The operation by itself reduces considerably the plasma ascorbic acid, according to the severity of the surgical procedure. This level remains low during a long or short interval according to the postoperative complications and treatment.

The author found that it is possible to maintain an almost normal plasma ascorbic acid level before and after the operation with the administration of 1,000 mgm. of ascorbic acid every 24 hours.

The determination of the white cell platelets ascorbic acid gave different results in different patients. When the general condition was good and the patient was a good risk, the white-cell platelet level did not change with the operation, even when the plasma level was zero. In one patient with esophageal cancer and artificial alimentation through a gastrostomy the plasma and white-cell platelets were both found deprived of ascorbic acid, a condition which represents a prescorbutic state without clinical evidence.

The amount of ascorbic acid in muscle and lung tissue removed during the operation seems to be below the values considered as normal by different authors.

The author draws from his studies the conclusion that all patients with chronic surgical chest conditions should be given high doses of ascorbic acid before and especially after important surgical procedures.

Harper W. H., and Blain, A., III: The Effect of Penicillin in Experimental Intestinal Obstruction. *Bull. Johns Hopkins Hosp.*, 1945 76 3

The purpose of this study was to reinvestigate the role of bacteria in producing death in dogs having isolated, obstructed jejunal loops, since antibacterial agents were not available to earlier workers in this

field. Potent antibacterial agents, especially penicillin, having no known important chemical or other reaction on the body were used. In studies on the problem of "toxemia" in relation to intestinal obstruction the use of the isolated obstructed loop is valuable because the factors of pancreatic juice, bile and decomposed food substances are eliminated, loss of electrolytes and water by vomiting largely obviated and the blood chemistry remains normal or nearly normal. The factors which remain and can be evaluated are the presence of bacteria, stasis, and distention.

In all dogs a portion of jejunum about 15 cm. in length was resected and its blood supply was left intact. Intestinal continuity was restored by end-to-end suture. Specimens for bacteriological study were obtained from the loop, which was then washed free of gross intraluminal material and closed at both ends by inversion. Fifteen dogs received no penicillin therapy and were used as controls. In 15 other dogs 50,000 units of penicillin in 4 c.c. of saline solution were introduced into the loop before it was closed, and 5 additional dogs were given large doses of penicillin intramuscularly starting at the time of operation.

All of the control dogs with isolated, obstructed high intestinal loops died within 6½ days. All of the 15 dogs in whose isolated loops penicillin was introduced were protected for 9 days, while 93 per cent were protected for 13 days, and 66 per cent were protected for over a month. Five dogs treated parenterally with penicillin were protected for more than 18 days.

Marked distention of the loop occurring in the presence of bacteriostatic agents is compatible with life. In the absence of distention of the loop as abundant bacterial flora uninhibited by bacteriostatic agents is compatible with life. These experiments indicate that distention must be present before infection of the intestinal wall by the normal intestinal flora can occur.

Microscopic and bacteriological evidence is presented to show that penicillin given prophylactically in large doses can prevent infection of the distended intestinal wall by the normal intestinal bacteria.

LEIOMYOSARCOMA OF THE STOMACH

Its Roentgenologic and Gastroscopic Diagnosis and Its Possible
Relation to Pernicious Anemia

RUDOLF SCHINDLER M.D. OLOF A. BLUMQUIST M.D. HAROLD L. THOMPSON
M.D. F.A.C.S. and ARTHUR M. PETTLER M.D. Los Angeles, California

LEIOMYOSARCOMA (leiomyoma malignum) is one of the rarest tumors of the stomach. It has been reported (7, 21) to comprise only 10 per cent of all gastric sarcomas. Since the frequency of sarcoma as compared to carcinoma of the stomach is said to be only 1:100 only one leiomyosarcoma should be expected to 1,000 cases of gastric carcinoma. Because we have observed 4 cases within a relatively short period of time, we feel that this statistical data may be misleading and that leiomyosarcoma may not be so rare as has been previously reported.

The diagnosis of this tumor is important because of its good surgical prognosis. The surgeon who may be inclined not to operate on large infiltrative carcinomas must nevertheless, consider the presence of a leiomyosarcoma which has a favorable prognosis and should not refuse to give the patient a chance as long as this tumor cannot be excluded.

It would be most desirable to make the differential diagnosis before laparotomy. The 4 cases observed by us were all examined gastroscopically. Although gastroscopy did not lead to the exact diagnosis the publication

of gastroscopic observations made on these patients seems to be justified because they may aid in better evaluating the gastroscopic findings in the future.

We have collected a total of 94 cases of gastric leiomyosarcoma from the literature. Sixty-eight of these cases were published by Chaffin in 1938 and since then at least 26 additional reports have appeared.

PATHOLOGY

The differentiation of leiomyosarcoma from benign leiomyoma is not easy. Transitions are to be expected theoretically. Cases have been described in which microscopically benign looking tumors had metastasized and thereby unexpectedly behaved like malignant tumors. Borrmann comments on this fact by saying:

Thus we cannot always recognize whether or not certain cells are malignant. None of the 4 cases of our own can possibly be called a simple benign leiomyoma inasmuch as they all show expansive growth not encountered in the simple benign myoma of the stomach.

Benign myoma of the stomach occurs frequently. Rieniets found 43 leiomyomas in 32 stomachs in 200 consecutive autopsies. These submucosal tumors are usually small and sharply circumscribed. Some may grow sub-

From the Department of Internal Medicine, College of Medical Evangelists, and the Los Angeles County Hospital, Los Angeles.

seriously others may grow toward the mucosa and finally protrude into the lumen of the stomach. They may become firmly fixed to the mucosa which often presents deep ulceration however the sharply limited rounded character of the tumor and the fact that it obviously belongs to the submucosal tissue makes it possible to recognize it grossly at once. The evenly rounded character of the tumor effects a recession between its surface and the surrounding mucosa. The recession is crossed in a characteristic manner by mucosal folds which if found all around prove that the tumor does not grow infiltratively toward the surroundings (19). Although transitional forms may occur it may be stated that in none of our four tumors did the gastroscopic observation reveal the typical picture of submucosal benign myoma. Microscopically the benign leiomyoma is composed of highly differentiated smooth muscle fibers.

Frequently malignant leiomyomas will not form metastases for a long period of time, but they quickly break their natural boundaries, grow expansively and partly infiltratively and prove to be fatal. The infiltration never reaches the degree found in infiltrative carcinomas, and frequently a limiting capsule is still present. Occasionally bridging folds may be seen (see our Cases 2 and 3) but they are much less marked than in benign tumors and usually are present only in a small portion of the circumference of the tumor. Most leiomyosarcomas are probably malignant from the beginning on, although sometimes sudden rapid increase in size of a long quiescent growth, with ensuing cachexia may be observed. Microscopically the muscle cells of these tumors are not so fully differentiated and evenly built as they are in benign leiomyomas. The fusiform cells may be shorter or rounded and irregular in form and show many stages of differentiation of the smooth muscle cell and mitotic figures in changing number may be found.

It is known that there are several gross forms of leiomyosarcoma (all of which were encountered in our own material). They may grow into the lumen of the stomach and may then even become pedunculated (Case 3) they may expand within the gastric wall

(Cases 1 and 4) or they may expand into the omentum or neighboring structures (Case 2). There is as little explanation for these different types of growth as there is for the different gross forms of gastric carcinoma. Ulceration of the mucosa covering the tumor is frequent in all forms.

The differential diagnosis between leiomyosarcoma and lymphosarcoma is particularly important because the lymphosarcoma reacts so well to x ray treatment (Buschke) while the leiomyosarcoma requires surgical treatment. In most cases these two forms of sarcomas should not be confused easily: the lymphosarcoma usually infiltrates the entire wall of the stomach, diffusely involving the entire organ (Bockus Schindler 15 16) although sometimes solid circumscribed tumors may occur (13). The leiomyosarcoma grows more expansively but less infiltratively. Exceptions may occur here too so that microscopic examination of a biopsy specimen is finally the best method for institution of adequate therapy.

The differentiation between leiomyosarcoma and carcinoma is more difficult. It has been said that on palpation the leiomyosarcoma has a rubbery consistency as contrasted to the stony hard palpatory sensation caused by carcinoma yet the gross differential diagnosis may be impossible.

Metastases were found in 15 per cent of our collected series. Cameron reports 20.5 per cent, but figures as high as 70 per cent appear in the older literature (Crohn). Metastases occur most frequently in the liver even without evidence of tumor formation in the regional lymph nodes. They occur but rarely in the lungs and bones. The metastatic liver tumors may grow only slowly. Lemon and Broders have seen a patient live 6 years with a metastatic nodule in his liver.

CLINICAL FINDINGS

The three cardinal findings are (1) gastrointestinal hemorrhage leading to anemia (2) epigastric or left upper quadrant pain (3) upper abdominal mass. Each occurred in about 50 per cent of the collected cases. Gastrointestinal bleeding is frequently severe and recurrent. The abdominal pains vary from a

vague distress to a severe ulcer like type of pain. The abdominal mass may sometimes fill the whole abdomen.

Nausea and vomiting do not occur frequently. Weight loss is usually only moderate in amount.

X ray examination and gastroscopy should at least reveal the presence of a gastric tumor. The most important findings will be described in the histories of our own cases. The difficulty in making of the x ray diagnosis will become apparent from our Cases 2 and 4.

In the collected series x ray examination revealed a filling defect in 59 per cent, an extrinsic mass was suspected in 18 per cent, stiffness of the gastric wall was described in 11 per cent, presence of ulcer niche without filling defect in 8 per cent, and in 4 per cent a negative gastrointestinal series was reported. In one case the correct diagnosis of leiomyosarcoma was made and this case will be discussed later in detail.

There are but few gastroscopic reports. Twice (5, 9) the tumor was overlooked at gastroscopy. Lemon and Broders stated that postsurgical recurrence of multiple leiomyosarcoma was seen gastroscopically. The first gastroscopic description of a leiomyosarcoma was given by Schindler and Letendre in 1942 (18).

CASE REPORTS

CASE 1. The gastroscopic picture of this case has been previously described (18). L. Q., a white male 26 years of age, was seen on October 22, 1940 at Billings Hospital, Chicago (Unit No. 251259). For 3 years he had had a gnawing feeling in the epigastrium and attacks of weakness after exertion. Once he had fainted. He had been treated for pernicious anemia; the blood count showed red cells down to 2,800,000 and seemed to have responded to liver treatment.

Physical examination revealed no abnormalities except some pallor. Hemoglobin was 11.6 grams, red blood cells 4,000,000, white blood cells 9,000. Gastric analysis showed 40 units of free hydrochloric acid after histamine.

November 4, 1940 x ray examination of the stomach (Frederick Templeton) revealed the presence of large neoplastic masses. These seemed to be benign but they were so large that one cannot be sure that they are not malignant. Spectacular degree of polyposis.

November 6, 1940 gastroscopic examination (R. S.) report follows: "The whole stomach was seen and the picture was one which I have never seen before (Fig. 1). The angulus was seen and below it there

Fig. 1. Gastroscopic picture of leiomyosarcoma. Case 1. Tumor masses protruding from the posterior wall covered by smooth soft mucosa. At 4 o'clock longitudinal ulceration. At the left side atrophic gastric mucosa with blood vessels.

was a soft protruding mass which filled almost the entire antrum. The mucosa covering it showed many dark creases and folds. A dark hole in its upper portion seemed to be the way to the pylorus. Although this mass was unusually soft I would not be able to exclude a malignant tumor from this picture alone. But then other protrusions were seen—5 along the posterior wall and 3 along the lesser curvature. Those of the posterior wall were large hemispherical protrusions which however, sloped gently toward the gastric wall. They all were covered by a smooth and soft mucosa and no stiffness was observed. However the highest of them lying in the fornix, had a somewhat different appearance. Its surface was nodular and had a definitely polypoid character. The three protrusions of the lesser curvature were smaller, the two lower ones having about the size of a cherry and the highest the size of a plum. They were covered by smooth mucosa. Their elevation was partly so that a shadow was cast on the surrounding mucosa but in other portions of the circumference there was a gradual sloping. The uppermost of these three formations contained many nodes of different size and if we had seen this one alone we would not have been able to differentiate between a benign and a malignant adenoma. Its combination with many other tumors speaks for a benign polyposis. The mucosa surrounding the highest of these tumors and of the whole upper third of the stomach was grayish in color with branching blood vessels. It should be mentioned that in the groove between the highest and the next highest excrescence of the posterior wall there was a dark, red, small depression which might or might not have been a small ulceration.

Impression: (1) polyposis, (2) atrophic gastritis of fornix, (3) it is impossible to exclude malignant degeneration of the stalks of the nodes.

On November 11, 1940 an exploratory laparotomy was carried out (Dr. H. P. Jenkins). The

Gastroscopic pictures drawn by Miss Eve Vermeade.

Fig. 3. Gross specimen. Case 1. Nodule mass in posterior wall and lesser curvature. Ulcer.

stomach was opened; extensive tumor masses within the wall of the stomach were found. A biopsy specimen of one of them was taken. Its microscopic examination revealed leiomyosarcoma. Thereupon

a course of x-ray therapy was given with a total of 4,000 r's.

On February 21, 1947, a second operation was performed (Dr. Lester Dragstedt). No change was found in the size of the tumor masses as compared with that at the first operation; the x-ray irradiation had been ineffective. Gastrectomy, splenectomy, partial pancreatectomy, and esophagogastrostomy were carried out. The patient recovered. He received liver treatment and was doing well on September 6, 1947.

Gross specimen. The gross specimen consists of the entire stomach, spleen, and a small portion of the tail of the pancreas. The stomach contains a large, firm mass in the posterior wall and lesser curvature—10 by 6 by 6 centimeters (Fig. 3). It is nodular and firm but not hard. Its serosa is intact and the mucosa is also intact, except over one large protuberant node where it is ulcerated; the floor of the 1 centimeter-sized ulcer penetrates for at least 1.5 centimeters into the tumor mass. Over others of the nodes there are small areas of hemorrhage in the mucosa. The cut surface of the mass is firm, white, with a slight hemorrhagic discoloration at the center.

Microscopically (Figs. 3 and 4) the tumor mass is composed of round and spindle cells with a moderate amount of eosinophilic cytoplasm. There is a slight degree of anaplasia of the tumor cells. Mallory stain reveals only a very fine reticulum in the tumor mass. Phosphotungstic acid hematoxylin stain shows no myofibrils. There is very little difference between this specimen and the biopsy specimen taken before radiation therapy. Pathological diagnosis: leiomyosarcoma.

Summary. A 25-year-old man had been treated under the diagnosis of pernicious anemia, but x-ray examination revealed large tumor masses of the stomach. Although malignant growth was considered, the diagnosis of polyposis was made. The same diagnosis was made at gastroscopy, although retrospectively it must be admitted that the picture

Fig. 5. Photomicrograph, Case 1. Survey section through rather normal gastric mucosa and adjacent tumor.

Fig. 4. Photomicrograph, Case 1. High power. Irregular sarcomatous tissue. Some typical smooth muscle cells.

Fig 5 Case 2 a, left, Roentgenogram taken before gastroscopy with complete filling, no pathology demonstrable b, After gastroscopy—relief method. Shallow filling of lesser curvature with niche formation. Two fistulas extend into the depth of the tumor.

described in the gastroscopic protocol ("never seen before—") was not consistent with the diagnosis of polyposis; the possibility of malignant tumor was considered. A biopsy specimen taken at an exploratory laparotomy revealed leiomyosarcoma. X-ray treatment was not effective. At a second laparotomy total gastrectomy with splenectomy and partial pancreatectomy was carried out. The patient recovered.

CASE 2 A S 56 year old white male No. 864521 entered Los Angeles County Hospital on December 21, 1943, with the history of melena which had occurred 24 hours before. In the afternoon of that day he suddenly felt sick, nauseated and vomited a cupful of dark blood. For 10 years he had vague abdominal distress occurring hours after meals and relieved by food. There had been no recent weight loss.

Physical examination revealed a well developed, well nourished male. Slight pallor of the visible mucous membranes was present. There was mild epigastric tenderness but no mass was felt. The hemoglobin was 56 per cent. Occult blood was found in the feces.

On January 26, 1944, the patient, after bed rest, dietary treatment and transfusions, had recovered so much that x-ray examination seemed permissible.

First x-ray examination. The upper gastrointestinal series did not show anything abnormal (Fig. 5a) except spasticity of the duodenal bulb consistent with early shallow ulcer. This diagnosis seemed clinically acceptable and the patient was in such a good condition that his discharge was planned. He

was seen by one of us in consultation, however, and advice for gastroscopy was given in order to determine if possible the true origin of the bleeding.

Gastroscopy was done on February 11, 1944, by Dr. David Niemitz and one of us (R. S.) (Fig. 6).

The instrument encountered resistance at first at the cardia, which was suddenly overcome and the instrument went into the depth of the stomach. The angulus and pylorus were in the two o'clock position and a picture was even obtained in the three o'clock position. There was some dullness and formation of nodules in the lower anterior wall. As the instrument was withdrawn a hemispherical tumor entered the visual field at the six o'clock position (see Fig. 6). It was covered with smooth, very pale mucosa. No ulcer or necrosis was seen. Higher up the tumor was so close to the instrument that no detail could be made out. The tumor extended up to the cardia, was 8 centimeters in length. Impression: (1) tumor of greater curvature and posterior wall below the cardia. *Carcinoma is most likely, however, a benign tumor, especially myoma, may be present.* (2) distortion of the lower portion of the stomach. (3) mild hypertrophic gastritis of the lower portion of the stomach.

Because of the tumor seen a repeat x-ray examination was suggested.

Second x-ray. At this second examination, February 16, 1944, care was taken to examine the relief of the mucosa and the patient received only one swallow of barium (Fig. 5b). Two niche-like protrusions are seen on the posteromedial side of the stomach at the junction of the proximal and middle

Fig. 6 Gastroscopic picture. Case I the upper third of the stomach a round mass tumor was seen protruding from the greater curvature and posterior wall.

third. These measure 2 centimeters in length and probably represent a perforation which in view of the gastroscopic findings could be into a neoplasm. The rugal pattern of the stomach is essentially normal (except in the area of the niches) but the cardiac end of the stomach appears to be displaced laterally and anteriorly by a soft mass. The findings are consistent with a perforated gastric ulcer with an adjacent inflammatory mass or—less likely—perforation into a carcinoma.

As the gastroscopic diagnosis of a tumor seemed perfectly reliable surgery was advised.

Operation was performed by Dr. H. Schiffbau on February 24, 1944. A large tumor mass of the posterior wall was found. Total gastric resection proved feasible. The spleen was removed. The tumor was found to be firmly adherent to the tail of the pancreas so that resection of the tail of the pancreas became necessary. No metastases were found.

The patient survived the operation a week later was in excellent condition, and made an uneventful recovery. He reported on September 30, 1944, that he felt fine. There was no recurrence of bleeding or any gastrointestinal distress.

Gross pathology. The gross specimen is pictured in Figures 7 and 8. Figure 7 shows the resected spleen, tail of pancreas and the posterior wall of the stomach containing an irregularly round tumor with node formation measuring 15 by 10 by 6.5 centimeters. In Figure 8 the upper half of the stomach has been opened across the anterior wall. In the posterior wall toward the lesser curvature there is an irregular ulcer 5 by 6 millimeters in size. Obviously this ulcer corresponds with the niche formation observed at the second x-ray examination (Fig. 5b) and it was missed gastroscopically because of its location in the well known "blind area" of the posterior wall (16). Close to its lateral margin a smooth rounded protrusion can be seen. It is caused by a node of the tumor and was seen and diagnosed at the gastroscopic examination. In the picture of the gross specimen there are bridging folds at the

Fig. 7 Gross specimen. Case I. Posterior surface. At left is the spleen, at right the expansively growing leiomyosarcoma of the upper portion of the stomach, beneath it (crossing the stomach) the tail of the pancreas.

lower pole of the tumor. Unfortunately at gastroscopy the tumor bulged so much that the lower recess with these typical folds was not seen. The large tumor is found at the left side of the picture. It extended into the gastrocolic omentum and into the pancreas.

Microscopically the typical picture of leiomyosarcoma is seen (Fig. 9). At some places rather regular smooth muscle cells are found. But in other places the cells are irregular only few nuclei still have the characteristic regular elongation with rounded edges of the normal nucleus of the smooth muscle cell. Most of them are oval or round, of various sizes and mitoses are observed. Most portions of the gastric mucosa (except that of the ulcer area) of the muscularis mucosae and even of the submucosa covering the tumor are perfectly normal.

Summary. A large leiomyosarcoma was found in a 56 year old male which probably had developed over a period of about ten years and had caused only mild epigastric distress. Acute hemorrhage led to hospitalization. At the first x-ray examination the tumor was overlooked because no relief technique was used. Gastroscopy revealed the presence of the tumor but the picture as seen was not exactly that of a carcinoma because the surface looked unusually smooth however it did not correspond with that of a benign myoma because the tumor extended diffusely toward the cardia. A second x-ray examination with relief technique revealed an ulcer niche. At surgery a leiomyosarcoma was found growing

Fig. 8. Gross specimen. Case 3. Anterior view. Upper two-thirds of stomach opened across the anterior wall. At the left side the huge tumor at right upper corner the spleen. The inside of the stomach shows the ulcer demonstrated by x-ray on Figure 5a, and the tumor protrusion seen at gastroscopy (Fig. 6)

expansively into the omentum and pancreas. Total gastrectomy with extirpation of the spleen and the tail of the pancreas led to cure which because of the good limitation of the tumor and the absence of metastasis may be permanent.

CASE 3 W B a 60 year old white male No. 104075 entered the White Memorial Hospital Los Angeles on July 11 1943 complaining of increasing weakness for 1 year. For 8 months he had suffered from distress in the left epigastrium occurring 4 hours after meals and which was promptly relieved by eating. About 2 months prior to entry he became dyspneic on mild exertion and noticed numbness and tingling in his extremities. Physical examination revealed marked pallor of the mucous membranes. The liver edge was felt just below the costal margin. No abdominal mass was felt and there was no tenderness. Hemoglobin was 6.3 grams red blood cells 900,000 color index 1.0 leucocytes 3,900 reticulocytes 0.5 per cent. Gastric analysis failed to reveal any free hydrochloric acid with the histamine test.

A tentative diagnosis of pernicious anemia was made. Treatment with parenteral liver extract was begun and 6 days later the reticulocytes rose to 22 per cent. After 8 days the hemoglobin rose to 8.8

Fig. 9. High power photomicrograph, Case 3. Irregularly formed sarcomatous cells. Mitoses.

grams red blood cells 1,960,000 and leucocytes 8,500.

The first x ray examination of the stomach was done on July 15 1943 (Dr. Stilson) with the following report: The stomach is of average tone. The major portion of its lumen is regular and flexible. The cardiac end of the stomach however on the film appeared rather peculiar and it is evident that the stomach empties rapidly. Probable neoplasm of the cardiac end of the stomach.

The second x ray examination was carried out by Dr. W. L. Stilson on July 19 1944 after the first gastroscopy. The report read: Now there are demonstrated definitely fluoroscopically and on the films extensive filling defects involving the proximal portion of the stomach, except the extreme cardia and extending for a distance of approximately 9 centimeters. The lesion apparently arises about 3 centimeters distal to the cardia.

The x ray pictures are partly rendered in Figures 10 and 11. In Figure 10 only the colon is filled with contrast meal but the stomach is empty. Here a tumor can be seen very well as a shadow within the air bubble of the stomach. Figure 11 demonstrates the large filling defect in the barium filled stomach. One should notice that no central crater is definitely visible though the barium accumulation at the lesser curvature side of the tumor may be interpreted thus.

Two gastroscopic examinations were carried out.

First gastroscopy (O.A.B.) on July 18 1944. The pyloric end of the stomach was well seen and several peristaltic waves could be seen running down to the pylorus the entire circumference of which came into view. Just above the angle along the lesser curvature there were 2 or 3 rather prominent folds which seemed to be somewhat redder than the surrounding mucosa which was extremely pale. About 5 or 6

Fig. 3. Case 3. Fundus of the colon is filled. The stomach is empty. The tumor is outlined toward the dark background of the gastric air bubble.

centimeters above the angulus on the anterior wall, extending down to the greater curvature a well defined mass could be seen. This mass was very red and succulent in appearance in contrast with the extremely pale surrounding mucosa, and there seemed to be several finger like processes. When the instrument was withdrawn the large red mass came in contact with the objective and it was impossible to see its uppermost portions. Along the posterior wall and greater curvature in the lower part of depth II, blood could be seen lying between the rugal folds but no point of active hemorrhage could be seen. In all portions of the stomach which were observed the mucosa was extremely pale almost to the point of whiteness.

Impression (1) carcinoma of the stomach involving the anterior wall and greater curvature of the upper and midportions of the stomach. (It was impossible to visualize the margins of this tumor mass and hence I cannot be certain that it does not extend all the way up to the cardia) (2) no gastritis seen."

Second gastroscopy (O.A.B. and R.S.) on July 30 1943. Immediately with the objective turned to nine o'clock extensive pathological changes were seen. A stiff protruding area bulged into the cavity of the stomach from its anterior wall involving the greater curvature also. At its deepest point there was a dark red protuberance and to both sides of this protuberance was a less dark wall surrounding the stiff area. This wall hung over in a mushroom-like fashion and pale pink, soft normal mucosa was submerged beneath the margins of the mushroom-like wall. On the top of the stiff elevation there was extensive white necrosis or ulceration. When the instrument was withdrawn the infiltrated area came

Fig. 4. Case 3. Stomach filled. Trudekburg position. Large filling defect.

close to the objective. The wall, however could be followed all around the lesion. It became much thinner in the upper portions of the stomach but remained sharply limited from the surrounding pale mucosa which its dark color formed a decided contrast. In the pale mucosa no sign of atrophy, no thinning, and no blood vessels were seen. Toward the upper edge of the wall several mucosal folds emerged as if they were running up the wall in a manner usually only seen in a benign ulcer (see Fig. 12). There was no infiltration. The upper limit of the wall was found to be 6 centimeters below the cardia. Impression (1) large carcinoma of the anterior wall and greater curvature of the body of the stomach (This is most likely a Type II carcinoma according to the classification of Borrmann. These Type II carcinomas usually give an excellent surgical prognosis) (2) No gastritis visible.

On July 3 1944, a gastric resection with anterior pyloric anastomosis was performed leaving only a small amount of the subcardial portion of the stomach (Dr. George Thomason). The patient recovered. The gross specimen contained a pedunculated tumor of the cardiac end of the stomach. This pedunculation is not well demonstrated in the picture of the gross specimen (Fig. 13) which demonstrates more the gross appearance. The tumor was 6 centimeters in diameter. Its surface was rough, irregular and contained three large ulcerated areas. A Type II Borrmann carcinoma was diagnosed at gross inspection.

Microscopically the tumor consists of smooth muscle tissue. The cells are partly regular and well

Fig. 12. Gastroscope picture. Case 3. At the left lower margin the fold of the cardia is seen. It is separated by normal mucosa from the upper edge of a tumor. The protruding tumor has a nodular wall and contains a large ulceration. Note especially the one 'bridging fold' running from the normal mucosa up to the tumor wall because of its diagnostic significance.

Fig. 13. Gross specimen. Case 3. At the right side of the large tumor there is extensive ulceration. The pedunculation does not show.

differentiated, partly irregular in form and without complete differentiation (Fig. 14). Scattered between the solid tumor masses are nests of plasma cells and macrophages. Where the tumor pierces the mucosa there is no sharp capsule. The neighboring mucosa shows some cysts at the bottom of the glands.

The mucosa of the anterior wall and lesser curvature distant from the tumor shows mild but definite changes. The interstitium between the long body glands contains few cells, mostly plasma cells and fibroblasts. The muscularis mucosae itself is split up. Between the muscle fibers are inflammatory cells. Most of the body glands are normal but some pits are proliferating toward the depth and at a few places metaplasia into an intestinal type of epithelium is seen. The surface epithelium shows mild but definite proliferation and between the pits there is some slight edema. Thus there is a mild but definite atrophic gastritis present. (It may be said here that this picture in our opinion is compatible with the diagnosis of pernicious anemia. It is of interest, furthermore, that this mild degree of atrophic gastritis was not recognized at two gastroscopies.)

Six months later the patient complained of swelling of the legs and of anorexia, but under continued liver treatment the distress disappeared. The blood picture remained normal. However, the patient was constantly treated with liver injections.

A third gastroscopy was undertaken on July 23, 1944 (O.A.B.). The gastroscope entered the jejunum; no tumor was seen. The gastric mucosa looked pretty normal but toward the cardia there was some thinning with blood vessels—atrophy of gastritis—not seen at the previous gastroscopies.

The patient was last seen in March 1945 at which time he felt quite well. Repeated x-ray examinations have failed to reveal any recurrence of the tumor. There was immediate emptying of the stomach stump.

Fig. 14. Photomicrograph. Case 3. The gastric mucosa contains cysts and 'cock-screw' glands—first signs of atrophy. The myomatous tumor at its break through the stomach wall has no capsule.

Fig. 5. Case 4. Roentgenogram interpreted as normal. However! the fornix contour and fleck are seen which may be interpreted as the outline and central ulcer of the tumor

resected specimen this tumor was found to be a pedunculated one but only at microscopic examination was the diagnosis of leiomyosarcoma made. Retrospectively it must be admitted that the second gastroscopic examination (Fig. 12) had revealed a feature which should have been considered as almost incompatible with the picture of gastric carcinoma, namely the presence of a bridging fold as described previously (19) as characteristic of submucosal tumor. The very large ulceration and the high dark red wall surrounding the ulceration reminded one so much of the frequently observed pictures of gastric carcinoma that the importance of this one fold for the correct diagnosis was underestimated although the gastroscopic protocol stated the presence of such a bridging fold "usually only seen in submucosal tumors".

The tumor was removed by extensive resection and the patient is living now in satisfactory condition. Of special interest is the blood picture obtained in this case. It will be discussed later.

CASE 4. E. T. a 46 year old Ethiopian female entered the Los Angeles County Hospital on January 16, 1941. One year before admission she had had hematemesis followed by occasional passage of black stools. She noticed increasing constipation and a weight loss of 60 pounds. Three weeks before

entry she became weaker and dyspneic. Repeated melena was observed. Twelve days before admission she vomited one pint of dark blood. She had had only a little epigastric distress.

Physical examination revealed an obese colored woman, with pallor of mucous membranes, rales at the base of the left lung and a systolic murmur over the mitral valve. On palpation of the abdomen no masses were felt. Gastric analysis revealed 85 units of free hydrochloric acid after histamine.

X-ray examination, February 20, 1941 revealed the following: Esophagus and stomach did not reveal any abnormalities. There was a normal 6 hour progress. The duodenal bulb was smooth. The hemoglobin which was 15 per cent on entry was brought up to 70 per cent after numerous transfusions. On March 10, 1941 the patient was discharged with the diagnosis of gastrointestinal hemorrhage of unknown etiology.

She re-entered the hospital on June 28, 1941 because of melena. The hemoglobin was down to 18 per cent. On July 14, 1941 x-ray examination was again undertaken. Normal six hour progress. Esophagus and stomach essentially negative. The duodenal bulb is small, but showed smooth outlines fluoroscopically. No tenderness, irritability or spasticity.

Gastroscopy (H.L.T.) was carried out July 3, 1941 and the report follows: Pyloric end of stomach normal in color and configuration except that there were multiple small pigmented hemorrhagic areas. In the proximal portion of the body there was a large necrotic ulcer with a fungating hyperplastic edematous margin typical of carcinoma. The high position and large size of the lesion makes its operability questionable. In view of the otherwise good general condition of the patient, surgical exploration is probably advisable.

X-ray films were taken again on July 25, 1941. Then a constant filling defect of the cardiac end of the stomach on the greater curvature side consistent with a polypoid neoplasm probably carcinoma was found. (If however Figure 16 of this x-ray examination is studied the conclusion may be drawn that there is a tumor of the cardiac end of the stomach with a central ulcer. The significance of this picture will be discussed later.)

On July 31, 1941 total gastrectomy with splenectomy and partial pancreatectomy was carried out (Dr. Harlan Shoemaker). The patient died post-operatively on August 5, 1941 from massive pulmonary atelectasis.

The gross specimen consisted of the excised stomach which contained in the upper posterior wall a cartilaginous-looking mass measuring 5 by 11 by 4.5 centimeters with a large mucosal ulcer of its central portion. The tumor had grown expansively beneath the mucosa and extended to the serosa forming there a knobby projection.

Microscopically there are intertwining bands of elongated spindle-shaped cells. Few mitotic figures are seen. The regional lymph nodes do not contain

Fig. 16. Case 4. The diffusely infiltrative leiomyosarcoma has grown destructively into the gastric mucosa. Signs of atrophy.

any tumor cells. Figure 17 shows that the tumor invades and destroys the mucosa which contains only remnants of glands. Some of these may still be seen within the tumor tissue. Some show cystic dilatation.

An autopsy was performed by Dr L. K. Andersen. Massive atelectasis of the lungs was found. In the liver there was a firm nodule 2 centimeters in diameter on the posterior surface of the left lobe. Macroscopically it proved to be a leiomyosarcoma metastasis (Fig. 17) without capsule.

Summary. A 46 year old woman had had severe attacks of hematemesis and melena for over a year. The source of the bleeding was not found after the first admission and would have been overlooked at the second admission without gastroscopy. With this method an ulcerated tumor of the upper portion of the stomach was seen and interpreted as a carcinoma. Surgery revealed an intramural leiomyosarcoma. Total gastrectomy with splenectomy and partial pancreatectomy was performed. The patient died from massive pulmonary atelectasis. On autopsy one small metastatic node in the liver was found.

DISCUSSION

A brief discussion of the x ray diagnosis, gastroscopic diagnosis, relationship to pernicious anemia, and therapy of leiomyosarcoma of the stomach follows.

X ray diagnosis. In our material the diagnosis of a gastric tumor was missed at one x ray examination in Case 2 and at two x ray examinations in Case 4. In these 2 cases the

Fig. 17. Case 4. Photomicrograph showing liver metastasis. At left liver tissue. At right leiomyosarcoma tissue without capsule.

presence of a gastric tumor was found at gastroscopy. This rather poor result can obviously be improved. In both cases the tumor could be demonstrated at a repeat x ray examination when the proper technique was used. These 2 cases prove again the fact that the method of filling the stomach completely with barium suspension and then taking films is unsatisfactory. It must be replaced routinely by the relief method (22). With this method the relief of the stomach is studied and much finer lesions than those found in Cases 2 and 4 will not be overlooked.

The diagnosis of benign submucosal tumor at x ray examination can be dared if a sharply defined round filling defect with a central niche is noted. The central niche is characteristic of the central ulceration so frequently found in these tumors. However in leiomyosarcoma it may be more difficult to state that this tumor originates from beneath the mucosa, i. e. from the submucosa or muscularis propria. A case report published by Chaffin however shows how astonishingly correct diagnoses become possible if proper technique and deliberate interpretation are used. The x ray examination in that case was carried out by Dr D. R. Laing of Pasadena and the x ray protocol (May 28, 1936) read:

"The stomach is somewhat hypertonic. Near the junction of the distal and middle thirds of the stomach is an area approximately 5.5 centimeters in diameter which is not covered with barium except for an area 2 centimeters in diameter in its approximate center. There a few radiating lines extend from this center pocket of barium to the proliferation

of the rounded lesion. The stomach was very pliable. Peristaltic waves moved over very freely and were only lessened in this region to the extent that the lesion impinged on the respective curvatures. The rugal pattern was intact except in the area occupied by the lesion. The center of the lesion could be emptied of its barium by palpation. There was no tenderness in this lesion. The duodenal bulb filled readily and smoothly. The findings are suggestive of a solitary mass with central necrosis which may be due to sarcomatous degeneration. The possibilities of localized hypertrophic gastric mucosa or a large polyp with central ulceration or umbilication must also be considered.

Here proper interpretation had led to the correct diagnosis of a submucosal tumor. The central ulceration seen was interpreted in favor of sarcomatous degeneration. This is not correct. Perfectly benign submucosal tumors of every kind, even lipomas, may have similar central ulceration. In this case however definite leiomyosarcoma was found microscopically and the fact remains that the roentgenologist had stated correctly that a malignant tumor of the stomach had originated from the submucosal layers.

If we review critically the x ray protocols of our 4 cases, then we may say that in Case 1 probably the correct diagnosis of a tumor originating submucosally was impossible. Large neoplastic masses were seen, they appeared benign but malignant growth could not be excluded. However at the examination of the excised gross specimen an ulcer was found and the floor of this ulcer penetrated for at least 1.5 centimeters into the tumor mass. This indicates a kind of fistula formation. Such a fistula might have been seen at x ray examination. In carcinoma this feature is observed rarely if ever.

Case 2 shows that this sign may be demonstrated at the x ray examination of leiomyosarcoma. At the second x ray examination the picture rendered in Figure 5b was obtained. A shallow filling defect is seen with an ulcer niche formation. Two fistulas extend into the depth. Each of these fistulas has a length of 2 centimeters. They were described well in the x ray protocol. In consideration of a similar picture in the gross specimen of Case 1 we conclude that filling defect with central niche and fistulas at x ray examination is rather characteristic of leiomyosarcoma.

In Case 3 the tumor was at first seen best as a round shadow within the gastric air bubble. Later a round filling defect within the barium was seen. The diagnosis of submucosal tumor was impossible at x ray examination because the tumor protruded into the mucosa and was pedunculated. We do not believe that at x ray examination the differentiation from carcinoma in this form of leiomyosarcoma is possible.

In Case 4 two x ray examinations had failed to reveal the tumor. After gastroscopy at a third x ray examination. Polypoid neoplasm, probably carcinoma was found. But if we look at this picture (Fig. 15) then we see a central niche within a tumor of the fornix and this central small crater may have suggested perhaps presence of a submucosal tumor.

Thus we come to the conclusion that in 3 of our 4 cases the x ray diagnosis of a submucosal tumor would not have been entirely impossible. It must be admitted that in some cases (as in our Case 3) the differentiation from carcinoma at x ray is impossible but the x ray syndrome of filling defect plus central niche plus fistulas should be considered as highly suggestive of leiomyosarcoma.

Gastroscopic diagnosis. In none of the 4 cases was the correct diagnosis made at gastroscopy but in 2 of the cases (Cases 2 and 3) features were described in the gastroscopic protocols which had a certain relationship to submucosal tumors, and this relationship had been stated.

If we analyze the gastroscopic pictures of the 4 cases, we find that in Case 1 the gastroscopic protocol offers no foundation for the final diagnosis of 'polypoid'. The gastroscopic findings correspond with every feature later found in the gross specimen. This gross specimen has no similarity to the well known picture of gastric polyps. The protocol states that in the antrum a soft, protruding mass was seen. Other large hemispherical protrusions were described which sloped gently toward the gastric wall. The elevation of other small protrusions was 'partly so that a shadow was cast on the surrounding mucosa but in other portions of the circumference there was a gradual sloping. This description does not

fit with any picture of carcinoma neither does it correspond with the known pictures of lymphosarcoma. It certainly should not have been interpreted as polyposis. We believe that the appearance of the antrum alone would have permitted the diagnosis of a sarcoma.

In Case 2 the correct diagnosis of a tumor was made. It was then stated that Carcinoma is most likely however a benign tumor especially myoma may be present. The latter tumor was considered because of the smoothness and roundness of the tumor seen. The consideration of carcinoma and of myoma came pretty close to the truth and one cannot consider this diagnosis as entirely wrong. The gross specimen showed bridging folds at the lower pole of the protrusion but these folds the observation of which should have established the diagnosis of a submucosal tumor were not seen at gastroscopy. It seems that these folds usually are numerous and present at all sides of a benign submucosal tumor but they are only occasionally seen if the submucosal tumor starts to grow expansively and infiltratively.

Only one such fold was noticed in Case 3 (Fig. 12). Its presence should have forced the observer into the correct diagnosis in spite of his unwillingness to assume another case of leiomyosarcoma. We quote here the decisive sentence of the protocol in order to show how reliable such apparently minor gastroscopic signs are: toward the upper edge of the wall several mucosal folds converged one of them running up to the wall in a manner usually seen only in submucosal tumors.

In Case 4 the gastroscopic appearance was that of a carcinoma, and retrospective analysis reveals no sign which could have been interpreted as characteristic for a submucosal tumor.

Thus we come to the conclusion that in 3 cases (1, 2 and 4) the x-ray diagnosis would not have been impossible and that in 3 cases (1, 2 and 3) the correct gastroscopic diagnosis should have been made. The preoperative diagnosis of leiomyosarcoma of the stomach is in the realm of possibility.

Relationship between leiomyosarcoma and pernicious anemia. The frequency of benign adenomas in pernicious anemia is well known

(Brown Schindler, 17). More and more the opinion gains ground that carcinoma develops secondarily to pernicious anemia more frequently than should be expected. However no such relationship is known between pernicious anemia and tumors of muscular tissue.

In our material twice a pernicious anemia was diagnosed (Cases 1 and 3). This diagnosis was obviously wrong in Case 1 in which free hydrochloric acid was found at the histamine test. In Case 3 the clinical picture was that of pernicious anemia. The hemoglobin was 63 grams with a red count of only 900 000. The color index was 2.0. The white count was 3 900. There was 0.5 per cent of reticulocytes. After liver therapy there was a typical response: the reticulocyte count went up to 22 per cent. There was no free hydrochloric acid in the gastric contents at histamine test. The gastric mucosa did not show any sign of inflammation at gastroscopy but by microscopic examination mild but definite atrophic gastritis was found. Schindler and Serby (20) described cases of untreated pernicious anemia in which only partial atrophic gastritis was seen and one case in which no atrophy at all was seen but only superficial gastritis. The conclusion must be drawn that pernicious anemia is not necessarily accompanied by severe or complete atrophy but that mild inflammation may be present as well. In this Case 3 everything speaks in favor of pernicious anemia being present.

Relationship between pernicious anemia and the gastric muscularis propria is known to exist. Koch described 3 cases of hypertrophy of the pyloric musculature in pernicious anemia. Mayeda described enormous thickening of the muscularis propria increasing from the cardia to the pylorus in a case of pernicious anemia. It is true that in cases of malignant tumor of the stomach macrocytic anemia has been observed but in all such cases the question remains open whether or not the macrocytic anemia preceded the tumor formation. Although we cannot exclude the possibility of a macrocytic anemia caused by the leiomyosarcoma of our Case 3 we want to suggest the possibility of the reverse sequence: namely pernicious anemia leading to formation of leiomyosarcoma.

Treatment The gross and microscopic observation in Case 1 shows that x ray treatment of gastric leiomyosarcoma is ineffective.

Surgery however proved to be eminently satisfactory. In one case (Case 3) extensive gastric resection was carried out. In the 3 other cases total gastrectomy with splenectomy and pancreatectomy was performed. Only one patient died postoperatively (Case 4) and this death was not due to abdominal catastrophe but to massive pulmonary atelectasis. Three patients survived the enormous procedure and seemed to be cured permanently. It is remarkable that these operations were performed by four different surgeons in three different institutions. Certainly surgery was in extraordinarily competent hands in all cases and there is no doubt that great progress has been made with the technique of such procedures as total gastrectomy and partial gastrectomy. Yet one may consider the possibilities that the vitality of patients with leiomyosarcoma may not be so affected as it is usually in carcinoma. In leiomyosarcoma the surgeon cannot be easily too courageous. The excellent results obtained in our series justify the attempt to remove even the largest tumors.

SUMMARY

1. Four cases of leiomyosarcoma have been described.

2. The possibilities of the roentgeologic and gastroscopic diagnosis of this tumor have

been discussed. Its possible relationship to pernicious anemia has been considered and the excellent results of surgical treatment have been described.

COMPOSITE FREE GRAFTS OF SKIN AND CARTILAGE FROM THE EAR

JAMES BARRETT BROWN M D F A C S Colonel MC A U S St Louis, Missouri and
BRADFORD CANNON M D Lieutenant Colonel MC. A.U.S., Boston, Massachusetts

FREE grafts consisting of two surfaces of skin with cartilage between can be considered for the replacement of tissue lost from areas such as the nostril border and tip and columella. These defects can be corrected in one procedure with the best resulting appearance of any method used.

This work has been done at Valley Forge General Hospital in association with Major Carl E. Lischer, Major Parke Scarborough, Captain Bowdoin Davis, Captain Andrew Moore, and Captain Joseph Murray.

there is minimal deformity of the donor site and the use of bulk flaps is avoided. The ear can be repaired with a local flap or by burying the open ear under a direct scalp flap from behind and freeing it and grafting the defect 2 to 3 weeks later.

The procedure is useful for tissue losses from burns, gunshot and shell fragment wounds as well as other traumatic or operative losses. It is necessary that there be a

Fig. 1. Illustrating the steps in repair of nostril border with composite free grafts of skin and cartilage. Drawing by T/S David G. Parsons.

Fig. 4. Complete restoration of ala in single operation. With composite free graft of skin and cartilage. Ear border already deformed by being shot through, used for ala before repair of ear with direct scalp flap. Flap detached 3 weeks later.

Fig. 5. Restoration of columella, tip, and ala in single operation by use of composite free graft of skin and cartilage. Notching of upper and lower lips has been corrected.

satisfactory minute blood supply in the recipient area and the defect has to be opened widely and deeply over a sufficient area. This procedure creates a larger defect to be filled than the original defect.

The size of replacement tissue of course is limited. So far the whole columella, tip and one border of the nose have been put in at one operation, also nostril borders on two sides.

A great bulk of tissue cannot be transplanted as a free graft; the maximum at present has been about 1 centimeter in width, length has not been important. The amount of available ear structure is also a determining factor; the part of the border containing cartilage being used. (In some instances, the ear border is already deformed and has to be repaired anyway so that no extra operation is

Fig. 4. Large replacement of nostril defect by use of free composite graft of skin and cartilage in a single operation. Minimal ear deformity with scalp flap restoration.

necessary. The desired graft is taken off for the nostril when the ear is repaired. In severe burns when both ears are largely destroyed the source is lost.) At operation the defect is prepared so that the area has a good minute blood supply. The graft is cut to pattern from a suitable portion of the ear in a region where cartilage presents just under the skin. Care is taken not to separate skin from cartilage. The crus of the helix can be utilized.

The graft is sewed accurately in place with fine sutures along all edges with one or two deep ones at the start.

The nostril is packed and a firm pressure dressing applied. The graft may become blue and discolored and even blister and careful attention and protection are required in its management.

Small areas of flat cartilage with overlying skin can also probably be done but enough observations have not been made to report this variation. This graft is taken from behind the ear and the skin is cut larger than the cartilage so that it can spread out and pick up a blood supply. These grafts necessarily have to be small and the skin over the cartilage probably survives because of a lateral blood supply coming in through the edges rather than by a supply through the cartilage.

SUMMARY

Sections of the border of the ear containing two surfaces of skin with cartilage in between have been successfully transplanted as free grafts and defects of the nostril border tip and columella have been repaired satisfactorily in a single operation.

SUBCUTANEOUS HEPARIN IN THE PITKIN MENSTRUUM FOR THE TREATMENT OF EXPERIMENTAL HUMAN FROSTBITE

KURT LANGE, M.D., and LEO LOEWY, M.D. New York, New York

WHILE numerous reports¹ have been published concerning the morphologic changes that occur in frostbite the literature concerning the functional pathology is scarce. Green's excellent studies of the pathologic changes occurring in experimental frostbite pointed the way for detailed investigation of the physiologic changes occurring in this lesion. The use of the fluorescein test (3, 4) was a medium through which the sequence of events could be observed in tissues exposed to severe cold. In this test small amounts of fluorescein are injected intravenously and the migration of the dye through the blood stream and the interstitial spaces is observed under long wave ultraviolet light.

As a result of studies in artificially frost bitten animals (5) it was established that for periods from 30 to 120 minutes following exposure to severe cold no fluorescein appears in the exposed areas thus indicating a severe spasm of the arterioles. This condition is followed by a second stage during which all blood vessels reopen and fluorescein can be seen throughout the exposed areas. The diffusion of the dye into the surrounding tissues in this stage is many times greater than it is in the nonexposed skin due to increased capillary permeability; the picture of intense hyperfluorescence in the previously frozen areas is thus produced. This period is also characterized by marked swelling of the exposed region. Eight to 14 hours after exposure a repeat fluorescein injection shows that now the exposed spots are nonfluorescent indicat-

ing a pregangrenous state. This nonfluorescence increases in the next hours until finally the entire focus is nonfluorescent and becomes gangrenous. Biopsy specimens taken at this time show that in agreement with the findings of Green and Kreyberg there is a clumping of red cells in the dilated smaller vessels. This clumping is probably due to loss of plasma through the highly permeable vascular wall. The red cells are stranded and fill the blood vessels, thus forming a sludge. They do not, however, represent *true* thrombi. The simple injection of saline enables one to wash out these erythrocytes as individual cells. Only after at least 72 hours does organization of these cells occur. This organization ultimately leads to infarctive gangrene. It is during the prethrombotic sludge phase that the therapeutic attack must be initiated to avoid thrombosis and ultimate infarctive gangrene as promptly as possible following exposure and ideally before thawing is complete.

Animal experimentation substantiated the fact that the timely use of heparin prevented gangrene whereas control untreated animals uniformly developed gangrene commensurate with the degree of frostbite.

It was now essential to apply these experiences to the human. The practical demonstration of the therapeutic value of heparinization in the prevention of gangrene was made possible by the study of artificial frostbite in human volunteers. These volunteers were recruited from patients who were being treated for subacute bacterial endocarditis by the combination of penicillin and heparin (6).

This investigation in human volunteers had a twofold purpose: first to corroborate animal experiments and second to evolve a simple practical method for the heparin treatment of frostbite. The subcutaneous heparin prepara-

tion in the Pitkin menstruum (7-9) seemed uniquely applicable in this connection. The intravenous administration of the aqueous commercial preparation of heparin would involve a more elaborate set up than the simple intramuscular or subcutaneous injection of the drug in Pitkin's menstruum. This method of depositing heparin achieves a consistent retarded, and equal release of the anticoagulant. The Pitkin menstruum which was designed to regulate the rate of release of water soluble drugs is composed of gelatine, dextrose, glacial acetic acid, and water in definite proportions.

Various formulae (Table I) have been developed containing variable amounts of heparin in the Pitkin menstruum with or without vasoconstrictors. The vasoconstrictors have an additive prolonging effect. By combining the injection of various ampuls, one is able to employ greater or lesser amounts of heparin with or without vasoconstrictors.

The method of administration is as follows: the contents of the ampuls are liquefied in hot tap water drawn up through a 2 to 5 inch 18 gauge needle into a 5 or 10 cubic centimeter syringe and injected subcutaneously, preferably into the anterior or lateral aspect of the thigh. The pain and discomfort is variable and transitory. The injections are given, as a rule, every day or every other day, and the average dose is 300 milligrams of heparin. Occasionally, 400 milligrams is required. The correct dosage is estimated by following the coagulation

time as determined by the Lee-White modification of H. Wells's method. By this method the average normal coagulogram is 9 to 15 minutes. Prolongation to 30 minutes to an hour is considered a satisfactory response. The response to the preparation is predictable in most instances as judged by observation of its clinical department in considerably over 1000 depositions administered in well over 200 patients suffering from subacute bacterial endocarditis or thromboembolic disease. The anticoagulant effect may be markedly depressed by the application of ice bags to the site of the deposit or may be accelerated by the local application of heat. Because of the urgency for obtaining prompt adequate anticoagulant effects in the treatment of frostbite, a larger initial dosage such as 400 milligrams was employed at times in conjunction with local heat. In this manner anticoagulant activity was observed within an hour.

Fig. 7. E.C., female. Two days after exposure to crucible filled with dry ice applied for 30 minutes to the upper arm.

Fig. 8. Same patient 8 days subsequent to the initial exposure and 4 days following a second exposure under the same conditions but which was followed immediately by heparinization.

Fig. 9. Same patient 20 days after the first exposure and 14 days after the second exposure which was followed by heparinization.

Fig. 10. Same patient 27 days after the first exposure and 3 days after the second exposure followed by heparinization.

The practical demonstration of the therapeutic value of the method was made possible in our study of artificial frostbite in eight human volunteers. In one group the frostbite was accomplished by means of a porcelain disc filled with dry ice and applied with pressure, to the skin of the lateral aspect of the upper arm for 10 minutes. An area about 2 centimeters in diameter came in contact with the skin. By this method a temperature of approximately minus 22 degrees C was achieved. Heparinization was started immediately following the exposure. One volunteer served as a control. The other group was subjected to local refrigeration in the same manner but for two exposures of 30 minutes each. The initial or control exposure was permitted to develop for 6 days before the second frostbite was induced immediately following which, treatment with the subcutaneous heparin in the Pitkin menstruum was initiated. The 30 minute exposure with dry ice results in temperatures considerably below minus 22 degrees C and is comparable as to the degree of exposure, to the frostbite suffered by aviators in high altitude flying such as nose gunners after demolition of the plexiglass protection or gunners attempting to unjam guns without glove protection.

The metamorphosis of the untreated lesions and the repair following heparin therapy are shown in the following illustrated cases.

CASE 1 S.F. male aged 33 years control case. The patient was suspected of having subacute bacterial endocarditis although no organisms had been recovered from the blood stream on repeated trial. He had been accepted for treatment with penicillin and heparin, which however had not as yet been started. A 10 minute application of dry ice produced a frosted depressed area 2.5 centimeters in diameter with surrounding raised erythematous zone 0.5 centimeters wide. The refrigerated area was frozen stiff. About 2 hours later the area of central depression was pink and elevated with a small zone of surrounding erythema. The following day the peripheral erythema about the frozen area had disappeared. The lesion was gray brown with superficial vesiculation and had become completely anesthetic (Fig. 1). By the fourth day the central gangrenous area with surrounding hyperemic zone had progressed further (Fig. 2). The lesion on the 17th day appeared as a healing lesion with the exception of a small central necrotic, ulcerated crusted area about 3/8 of an inch in diameter (Fig. 3).

CASE 2 S.Z. male aged 35 years suffering from subacute bacterial endocarditis due to a gram negative anaerobic coccus of the *Vellionella* group. He had several courses of penicillin heparin therapy and was at the time in a post therapeutic observation period. He was given a 10 minute exposure similar to that given S.F. following which he was immediately given 400 milligrams of heparin subcutaneously without vasoconstrictors (2 LP 11 Table 1). The coagulation time rose promptly to almost 40 minutes from a control of 18 minutes (Graph 1). The following day another 400 milligrams was given despite an adequate coagulogram of about 25 minutes in order to bridge the initial critical period with optimum anticoagulant responses. He was given another deposit of 350 milligrams (LP 11 plus LP 13) 48 hours later and 48 hours after that a final 300 milligrams (2 LP 13). The graph indicates constant and satisfactory heparinization. After 24 hours the initial depressed area was raised gray brown in color with a superimposed vesicle about 1 centimeter in diameter (Fig. 4). Four days after exposure there was marked hyperemia of the exposed area (Fig. 5). The entire lesion resolved without necrosis as shown by a comparable photograph taken on the 17th day following the exposure where almost complete healing is indicated (Fig. 6—see control Fig. 3).

CASE 3 E.C. female aged 21 years suffering from subacute bacterial endocarditis due to *Streptococcus viridans*. She was given a control frostbite by exposure to dry ice for 30 minutes. Two days after this exposure an enormous blister involving the entire lesion was at its height (Fig. 7). Six days after the control frostbite was produced, a similar 30 minute exposure was effected below the control area immediately following which 300 milligrams of heparin in the Pitkin menstruum without vasoconstrictors (2 LP 13) was deposited subcutaneously in the lateral aspect of the thigh. The coagulation time rose from a control of 12 minutes to 33 minutes (Graph 2) and dropped to 22 minutes the following day at which time an additional 300 milligrams (2 LP 13) was given with a prompt rise to 42 minutes. Thereafter, 300 milligrams (2 LP 13) was deposited every other day. Heparinization was constant and adequate with the exception of the 6th day. However it is more than likely that the effective therapeutic was accomplished within the span of the first 6 days.

Eight days after the control exposure the untreated lesion appeared as a large ruptured bulla with an indurated base. Necrosis was also evident. Two days after exposure, the heparinized frostbite lesion was large, bullous and without induration (Fig. 8). Necrosis of the control untreated area was still fairly extensive 10 days after exposure but the heparinized lesion 14 days after exposure showed merely hyperemia and dilatation of the blood vessels without loss of tissue (Fig. 9). The complete necrosis of the untreated area is effectively portrayed 27 days after the control exposure. This

contrasts with the almost complete healing of the treated heparinized lesion 22 days after exposure (Fig 10)

SUMMARY

1 The functional pathology of frostbite is discussed and the early heparinization of patients with such lesions is suggested.

2 Heparin in Pitkin's menstruum deposited subcutaneously or intramuscularly is a simple and satisfactory method of achieving effective anticoagulant responses

3 Eight volunteers were exposed to small areas of frostbite by the use of dry ice. None of them developed any tissue loss when ef-

fectively treated with subcutaneous heparin while the control lesions showed central necrosis.

MILITARY SURGERY—UNITED STATES ARMY— EUROPEAN THEATER OF OPERATIONS, 1944-1945

ELLIOTT C CUTLER M.D. F.A.C.S. Brigadier General, M.C. A.U.S. Boston Massachusetts

MISSION OF UNITED STATES ARMY MEDICAL DEPARTMENT

THE Medical Department of the United States Army has a threefold mission—first, evacuation of the wounded, both from the battlefield where their presence jeopardizes morale and from the Army hospitals, where their care infringes upon the mobility and supply of combat forces. The second function is that of professional medical care. For this purpose an organization must be set up that brings the battle casualty and the medical officer together and provides the medical officer with those facilities necessary for such care. The third function is that of the restoration of injured men to combat. The number and percentage of wounded who can thus be returned to combat may in a war of attrition dictate success or failure. The medical departments of other armies may have other objectives—certainly, our inability to capture wounded Japanese in any number suggests that the medical department of the Japanese Army has a different mission.

ORGANIZATION OF ARMY MEDICAL DEPARTMENT EUROPEAN THEATER OF OPERATION

To accomplish this threefold mission there must be a carefully integrated organization and some understanding of this is desirable if one is to appreciate the results which it has achieved. A primary consideration is the complete interdependence of administration and professional care, on which depends its effectiveness. The civilian doctor is prepared to expend every ounce of energy and all of his time on a single patient, knowing that others can be found to care for additional injured or sick people who might present themselves at the same time. This policy when one is confronted with thousands and

not individuals must be forgotten in the greater good for the larger number. This change of outlook from the individual to the mass is the chief difficulty confronting the civilian doctor when he enters military service. Moreover if the three functions of the Medical Department are to be fulfilled—evacuation medical and surgical care and restoration to combat fighting—attention must be focused more and more on those who can be returned to duty. By so doing eventually a greater good for humanity will be achieved for if large numbers of men can be restored to the fighting forces, war will end sooner and thus humanity suffer less. This need not result in neglect of the severely damaged soldiers.

The organization for medical care in the United States Army begins at the battle front and extends through to hospitals in our communications zone in a theater of war, from which the soldier may be returned to the combat forces or through to hospitals for rehabilitation in the United States of America. Charts 1 and 2 present graphically the course of the casualty from front to rear. The care of the wounded soldier begins on the battlefield there Company Aid men render first aid care. They control hemorrhage, dress the wounds, initiate sulfonamide chemotherapy, control pain with morphine, splint fractures and evacuate the wounded to the Battalion Aid Stations in the forward part of the combat division. The devotion and training of the medical soldier—of whom more than 2000 have been killed in action in this theater—has been a major factor in the good results achieved by the medical department in this theater. At the Battalion Aid Post where there is a medical officer in attendance, dressings are checked, splints readjusted, plasma is available if required, tetanus toxoid should be given, and the field medical record if it has not been initiated by the Company Aid

dize their opportunity to survive. Such may be those with multiple serious fractures. All other battle casualties by pass the Field hospital and go further to the rear to an Evacuation hospital. Thus sorting at the Clearing Station is a function of greatest importance and must be by experienced officers.

At the Clearing Station whole blood is available, and those who can travel following a transfusion of blood and/or plasma receive such treatment there. Also at this level treatment with penicillin is begun and from this point to the rear penicillin is available for regular parenteral injection. In the early part of the recent campaign sulfonamide therapy begun on the battlefield by the Company Aid man was continued to the Evacuation hospital, and a majority of individuals for a few months received simultaneous treatment with the sulfonamides and penicillin. As time passed and penicillin was in liberal supply the continued medication with sulfonamides gradually diminished until now it is practically reserved—other than the initial dose on the battlefield—for areas where penicillin is not available.

Each Army controls two special medical units—a Convalescent hospital and an Auxiliary Surgical Group. The Convalescent hos-

pital has 3 000 beds and usually has a policy permitting the holding there of soldiers who may be returned to duty within 10 or 14 days. If sick and wounded require a longer period they would not stop at the Convalescent hospital but pass to hospitals in the Communications Zone. The Auxiliary Surgical Group is an assemblage of 61 surgical teams the majority of which are headed by general surgeons though there are attached special teams in orthopedic surgery, neurosurgery, thoracic surgery, maxillofacial surgery and the treatment of shock. These surgical teams do the professional work in the Field hospitals, which are not staffed with expert surgeons and also bolster up the Evacuation hospitals where there may be an insufficient number of surgeons for the load imposed. The professional abilities of these team surgeons have played a major role in the diminution of mortality rates. The rapidity with which younger surgeons improved their technique and acquired judgment is a great tribute to their fundamental training in the medical schools of the United States of America. The existence of such an organization permits the movement of surgical teams at any time to an overloaded hospital and effects a saving in highly trained professional personnel.

The organization for care in the Communications Zone (Chart 2) is built around the professional work in General hospitals. These are ordinarily 1,000 bed institutions, capable of expanding to 1,500 beds but may be larger. Such General hospitals are frequently grouped together in what are called Hospital Centers which greatly increases the flexibility of care and evacuation and decreases the number of highly trained personnel required. Thus, if ten hospitals can be grouped together a service can be established in selected hospitals for the care of special types of injury. These are generally divided into centers for thoracic surgery, neurosurgery, maxillofacial and plastic surgery, and for the care of those injured in the hand. Because of the local situation in this theater we provided ourselves with hospitals of this type both on the Continent and in the United Kingdom. Early in the campaign all of the centers for such specialist care were in the United Kingdom and in these special hospitals the greater percentage of such care was accomplished. This grouping of casualties under highly trained experts led not only to splendid care of the individual case but provided sufficient material to permit critical evaluation of methods of therapy which led to a steady improvement in our technical procedures. Finally from hospitals in the United Kingdom or on the Continent evacuation both by air and sea had to be provided for the patients who could not be returned to duty and who should be returned to the United States of America.

This entire system of hospitalization is flexible, for it must vary with the military situation, since the tactical action and the numbers of casualties resulting from such activity dictate the theater policy for evacuation. Almost to the end of the campaign this theater functioned under a theater policy of 120 days, which meant that any sick or wounded soldier who could be returned to duty within 120 days could be held in the hospitals of the European Theater of Operations. Because of the difficulty of evacuating soldiers to and from the United Kingdom an additional policy was established relating to which cases should be hospitalized in the United Kingdom and which should be held in Continental hospitals.

As a rule long term cases went to the United Kingdom, and those who could be shortly returned to duty remained in Continental hospitals but when casualties were reaching between 40,000 and 50,000 per month, and when the Continental hospitals could not hold all those who would be returnable to duty in 60 days, or even in 30 days, modification of the policy came into being and many who were returnable to duty in 60 days or even less had to be evacuated to the United Kingdom and then brought back to the Continent when ready for duty. Similarly it was inevitable that in the rush of work (60,000 patients were moved by air in May) individual casualties who perhaps could never have been returnable to duty even in 120 days, were mistakenly routed and had to be held in our Continental units but these incidences must be looked upon as unusual.

All this emphasizes that only the perfect interdigitation of administrative and professional personnel can lead to a happy solution when thousands of wounded men are handled daily. Professional personnel must be informed where the load is to be borne, how long casualties can remain in one hospital, and what methods of evacuation are to be used if proper care is to be given. And personalities must be forgotten. In spite of difficulties, the professional group always attempted to carry out the policies set by the chief surgeon, both those which placed a time limit on professional care and that which demanded of us that the American soldier be given the best care possible under the conditions imposed by the military situation. Administration must set evacuation and hospitalization policies, but these policies and the burden they impose are borne by others. Good results will accrue only when both are completely informed of the labor and responsibility of the other. Directives are no substitute for good briefing, whether the goal be tactical or medical.

Sorting at the Clearing Station has already been dealt with. Further sorting is carried out in the Field hospital. Here with each admission an appraisal of the patient's condition will dictate what kind of resuscitation is necessary, whether the presence of a tourniquet demands immediate priority for the oper-

Chart 3. Battle casualties, Medical Department, European Theater of Operations, excluding K.I.A. Total battle casualties, 372,556; mortality rate, 3.9 per cent.

ating room or whether the missile's course and lodgment requires an x-ray examination before the surgical ordeal.

Again, after the surgical intervention further evaluation and sorting distinguishes between those who can stay and those able to be evacuated. The same kind of sorting evaluation, and triage must go on in every hospital. Let us consider the importance of proper sorting at the first General hospital the casualty enters after leaving Army installations. Here a dual function confronts the hospital—the wounded who have slipped through the Army hospitals without primary care must be given that care and those who have received primary care and those now given it in this hospital must be routed after sorting according to the evacuation policy at that time. Again consider the less busy General hospital in the rear-most area. Casualties may reach this hospital on the third or fifth day. The question immediately arises—which wounds can be sutured and which must be left open? All military surgeons must recognize that this constant evaluation and sorting into special categories for evacuation or professional care is a major function for the medical officer.

STATISTICAL DATA ON MORTALITY RATES AND DISPOSITION

Certain statistical data are presented at this point not to emphasize the immensity of the task now just completed but to demon-

strate that the results achieved in this war differ sufficiently from those in World War I to demand an estimation of the factors that have brought about these improvements. Also lessons may be drawn that will benefit our casualties resulting from the growing conflict in the Pacific.

Chart 3 summarizes the United States Armies European Theater of Operations total wounded in action casualties from D-day through V-E-day and presents the overall mortality rate of these casualties in medical installations. This mortality rate of 3.9 per cent in 372,556 battle casualties is approximately one-half of the rate in the first world war. Of the 3.9 per cent mortality, about 0.5 per cent die within the medical elements of the combat division (Battalion Aid Post, Collection Station or Clearing Station), 2.7 per cent die in Army hospitals (Evacuation and Field hospitals) and less than 1 per cent in General and Station hospitals in the rear area.

The next three charts present comparative statistics for anatomical woundings. Chart 4 compares the regional distribution of the wounds in the casualties reaching medical units alive in the United States Civil War, World War I and World War II. The increased percentage of wounds of the thorax and abdomen in this war as compared to World War I represents in part a higher survival rate, possibly through better care on the battlefield and better evacuation. Some of

directly contributing to the improvement of morbidity and mortality statistics, is the resuscitation of the wounded man. This transcends in importance any single method of therapy, such as our ability to procure and deliver blood and plasma to casualties, for it betokens that the American surgeon has at last appreciated the importance of the complete evaluation of his patients before therapy. He has learned to care for the whole of man and not for any fragment or any particular wound. This, in turn, has led to proper resuscitation and the better care of shock. Accretions to our knowledge concerning shock have come in steadily as experience has been acquired. Dependable studies of blood volume made in forward hospitals indicate that soldiers seriously damaged have averaged a loss of at least one-third of their total blood volume, and investigators have tried to set simple standards for recognizing this deficiency. Majors Emerson and Ebert have stated that a blood pressure below 85 systolic usually betokens a loss of over one-third of the total blood volume. Professor McMichael of the British Post Graduate Medical School has stated that in the male thigh an increase in diameter of some 2 centimeters which, to the cursory glance would not seem great, may mean that 1500 cubic centimeters of blood are outside of the capillary bed and actually beyond the vascular tree.

This is a matter of great importance. Surgeons are apt to think that only when there is visible blood loss is the condition of the patient jeopardized but it can be seen that 3000 cubic centimeters of blood may be lost from the circulation when there are wounds in both thighs, without more than a few drops leaving the body. It is this overall appreciation of diminution in the amount of circulating blood and this overall desire to look at the whole man and not the wound alone that has led to our greatest advance in this war. From May 22, 1944 to May 31, 1945 385,231 pints of blood have actually been used in medical installations in the European Theater of Operations. Of this, 194,712 pints were flown directly from the United States of America. This blood has been available as far forward as the Clearing Stations in Combat Divi-

sions. It has been used largely in the Field and Evacuation hospitals in the forward area at the time of primary surgical therapy and has been used in great quantities, up to 6 or 7 liters in a single individual in one day. This widespread use of blood through its easy availability has brought in its train inevitable reactions, as well as great benefit. The best figures available at this time show that about 4.8 per cent of transfusions are followed by some kind of reaction: allergic reactions, 0.9 per cent; pyrogenic reactions, 3.7 per cent; hemolytic reactions, 0.1 per cent. The reactions vary in different types of institutions, and vary as to whether the transfusion is given early or late. As a rule, primary transfusions have brought little reaction. Later transfusions, given in General hospitals, have often found the patient sensitized by the earlier transfusions. Pyrogenic reactions have increased where hospitals insisted upon cleaning their own glassware and not using sets furnished to them already clean and sterile. As time has gone on reactions have diminished, probably because of better technique, better refrigeration of the blood and through our ability always to furnish giving sets properly set up and sterilized at some central point. A particularly valuable study of these reactions following transfusion has revealed that the transfusion of large amounts of group O blood (the universal donor) and even of pooled plasma may result in serious hemolytic disease. The implication is strong that, whenever feasible, strictly compatible blood of the same group as the patient should be used; that where large amounts of group O blood must be used, only blood of a low titer should be administered. Such information as this, and other studies now in process, will doubtless have some influence on the future set up of blood banks in civilian life.

Chart 9 depicts the use of the varying anesthetic agents in over 360,000 cases. It is of interest to see as would be expected that the inhalation anesthetics are largely used in the forward hospitals for nontransportable casualties, comprising almost 45 per cent of all anesthetics in Field hospitals. This is because a high percentage of the wounded there are injured in the thorax and must have endotra-

Endotracheal	1	1.3	2.7	28.5	31	

cheal anesthesia. Another comment is suggested by the increasing use of regional or local anesthesia. It would seem that regional anesthesia is not, *per se* the anesthetic of choice when a wound must be widely debrided and much tissue excised. Regional anesthetics tend to limit the surgeon. They may thus result in inadequate débridement of the wound and unless there be other contradictory evidence it would seem wiser to render the patient insensitive as a whole for complete toilette of the wound. The high percentage of procedures carried out under intravenous (pentothal) anesthesia represents the usefulness and desirability of this method.

The débridement of the wound is the most important surgical task. It is of major importance for the end result, both as to life and as to function. If properly done it should obviate serious infection. It may preserve a limb from amputation and if blood supply is intact and major nerves undamaged will leave good function. In the first place the surgeon should always attempt to visualize the position of the patient at the time of the injury. This has been difficult to teach. Thus, a wound over the heart does not necessarily mean that the soldier is wounded in the heart for if the soldier was lying down the missile may have traveled a great distance under the skin and have done almost no damage and emerge close to the hip joint. Similarly if the arm is flexed when hit but operated upon in the extended position the tract of the missile cannot be properly débrided unless the arm is again placed in the flexed position as it was when the missile traveled across the bellies of the

muscles. We have watched a young surgeon attempting to find a missile in the inner condyle of a knee—a missile which entered when the knee was in the flexed position but the surgeon was operating upon his patient with the knee extended and thus failed for some time to locate the course of the missile and therefore unnecessarily damaged an important joint surface.

Another matter which must concern all military surgeons is what can be spoken of as wound ballistics or the application of physics to wounds. As early as 1914 it was shown that there was a definite relationship between the extent and severity of a wound and the kinetic energy (*i.e.* mass or size times velocity) of the missile producing the wound. The criterion put forward originally was that 58 foot pounds of energy were required to produce a casualty. However this original criterion was based on observations pertaining to bullets weighing an ounce or more. During the present war investigations have been carried out on the wounding power of very small high velocity fragments and it has been proposed that a new casualty criterion be set up on the momentary cavity which these missiles produce in tissues or experimental media. Although surprise has often been expressed at the large cavitation produced in soft media when a small missile passes through it it can be shown that this cavitation is to be expected and that the same physical principles apply to its formation in soft and hard media ranging from soft gelatin to hard steel.

When a missile passes through a medium that portion of the medium which lies just

ahead of the missile must move aside with a velocity somewhat less than, but comparable to that of the missile that has imparted some of its energy to the tissue. The extent of radial movement or cavitation of the tissue in the path of the missile depends upon the strength of the restoring force of the medium. Thus, the restoring force of steel or the tendency of the elasticity of the steel medium to reverse its direction of movement is great and the distance it moves radially along the path of a missile is minimal doubtless in most cases a small fraction of a millimeter. In contrast with steel, whose restoring force is approximately 100,000 times greater than 20 per cent gelatin (which is comparable in density to human skeletal muscle) in the latter a momentary cavitation is produced along the path of a missile passing through. Associated with the cavitation produced by a missile passing through a medium at a high velocity there is considerable damage to the medium at considerable distance from the missile tract. In instances where the medium is living tissue nerves vessels and even bones may be severed or broken when a high velocity missile passes in the proximity of but not necessarily through such a structure. An appreciation of these facts is essential to proper débridement of a wound and explains the necessity for wide débridement.

Let us now consider the actual carrying out of the débridement of a wound. In the first place proper preparation of the skin over a wide area must be performed. Soap and water is satisfactory but any good detergent such as ether gasoline or zephyran may be used. This may be followed by alcohol or if the surgeon is wedded to dyes, merthiolate. Next, the incision must be in the long axis of the body and sufficiently long to expose well every recess of the wound. A minimum of skin should be removed partly because skin is essential to proper early closure of the wound but also because skin itself is not alone the site of widespread infection. Only a minimum of 2 or 3 millimeters at the contacted edge of the tract need be cut away. Fascial planes below this should be widely opened and where there is tough fascia as in the thigh, it is better to cut this transversely as

well as longitudinally. When one is concerned with the next layer muscle, the major problem arises in the proper débridement of a wound. All devitalized and dead muscle should be excised. Hesitation to do this often results in disaster. Live muscle is determined by its ability to contract and by its color. If the wound is filled with salt solution after hemostasis dead muscle loses its color more rapidly than living muscle and all frayed fragments can be more easily detected. Once the surgeon is satisfied with the muscle excision which must in perforating wounds, involve both aspects of a limb he must carefully determine the condition of the nerves and blood vessels. These are the most important elements in an extremity. Blood vessels should never be ligated when the opening can be closed by a suture and if ligation seems essential, some form of tube if available should be inserted. The idea is to permit some blood to enter the extremity for at least 3 or 4 days until the collaterals have been given time to dilate and take over normal blood flow. In our opinion, heparinization of casualties, when there is the possibility of internal concealed hemorrhage, or where there are multiple wounds, carries too high a risk of secondary hemorrhage, and should be condemned.

Next one must be concerned with the nerves. If these are divided it seems wiser to approximate them loosely with a single loop suture of metallic substance such as tantalum. In order that one may find the severed nerve at the time the nerve suture should be carried out and to prevent their retraction to the deeper recesses of the wound. Suture of the nerve at this time in a contaminated area is not good therapy and in fact, it has been shown that the axis sheath is much more likely to accept and guide new processes into the sheath after an interval of 3 to 6 weeks.

Bony fragments, unless they are absolutely loose and unattached to the periosteum, should not be removed, for now that the danger of infection has been mitigated by the advent of the sulfonamides and penicillin we must leave every piece of viable bone in the wound in order that nature may reconstruct the damaged part herself. No bone graft can ever hope to equal natural healing. All soft

tissue wounds not leading to the cavities with in the skull the thorax and the abdomen must be left open in spite of modern chemotherapy infection remains a major risk which is vastly increased by primary closure of the wound.

Finally, the dressing As experience has accumulated it is obvious that much damage is done by packing wounds open. Ideally in very deep wounds a small slip of rubber tissue should suffice for the escape of tissue juices or a single piece of vaselined gauze might be left in such wounds. Next the wound must be properly bandaged. The advent of adhesive plaster has lost to the surgeon much of his art as a dresser, but the ideal dressing was well described by Sampson Gamgee almost 100 years ago, it should cover the wound completely and extend well beyond the wound to keep out further contamination. The dressing should contain enough substance so that when the bandage is applied it will be elastic and give gentle compression and comfort to the part. In turn, if the part is elevated swelling is diminished circulation is improved and pain is minimized as the sensitive tactile end organs are no longer stimulated by pressure. In the greater wounds it is wise to add further means of immobilization. This may be only a splint, or better a light plaster shell. The value of this immobilization of recently damaged tissue was perhaps overemphasized by the Spanish school, which felt that a limb should remain in plaster of paris until healing of the bone took place. Such prolonged immobilization led to a neglect of proper alignment of bone, though it did possibly assist, in the days before the sulfonamides and penicillin in decreasing the spread of infection. This debilitation of the wound is a major element in happy results. Chemotherapy has, indeed revolutionized modern military surgery and opened up immense possibilities in the earlier and more complete restoration of function. But chemotherapy cannot effect sterilization of dead and devitalized tissues surgery alone can be useful in such circumstances.

THE SURGICAL SPECIALTIES

Great advances have come during this war in each specialty. There are differences of

opinion as to whether the specialist has a place in the forward zone but the answer depends upon the definition of specialization. All surgeons whether they be in a narrow specialty or a large one should have first a broad general training in surgery. If this is the training of the specialist then he may be immensely valuable in the forward area.

Thoracic surgery has already laid down certain incontrovertible dicta for military surgery. First, conservatism in the forward area only, sucking wounds of the chest and pressure pneumothoraces and the greater wounds must be dealt with forward the majority of thoracic wounds except for the great necessity of keeping the pleural space emptied of blood do better with a period of delay and the more elaborate procedures when they seem necessary carried out in specialized hospitals in the rear area. The advent of chemotherapy has resulted generally in a decrease of serious infection in this field for work. A special word must be said for decortication of the lung a procedure which has proved satisfactory up to the third and even later than the fifth week following injury and also even when a very considerable amount of infection is present. The removal of a clotted hemothorax and decortication bears some relation to the removal of a subdural hematoma and indeed it may be that the increasing size of clotted hemothoraces bears a similar relation to the increased osmotic action of broken down hemoglobin as it does in intradural hematoma.

The field for neurological surgery has made great advances. In our Army those operated upon in the forward area are largely those actively bleeding threatened with increasing intracranial pressure or with very large retained missiles. It has been observed that less serious intracranial damage withstands transport very well and that in patients properly treated with penicillin the advent of serious infection is no greater when such patients must wait 3 to 4 days before reaching a hospital for specialized care in the rear area. In the field of peripheral nerve surgery equally important advances have been made. Our surgeons have made every attempt to close wounds as early as possible, and in the large percentage with nerve damage have sutured

Chart 10. Increased "salvage" with great proportion of secondary closures attempted.

procedure. Such a closure should be spoken of as delayed. It is not a secondarily closed wound because it was never closed before. It is not delayed primary closure because there has been no primary closure. We have had a large experience in this field. All our hospitals are instructed to close wounds at any time after the third or fourth day. The optimum time is certainly before 10 days, when granulation tissue and cicatrization have already begun to defeat any attempt to draw together the lips of the wound without a secondary cutting operation. It may be stated that around 75 per cent of all wounds are solidly healed 2 weeks or less after the delayed closure and that at 3 weeks 90 per cent are solidly healed. Variations in these percentages will occur with individual hospitals. The most difficult task in this field has been to persuade our surgeons to attempt to close all wounds. Some surgeons report statistics where 95 per cent of their wounds thus closed healed *per primam* but some of these surgeons do not attempt to close all wounds and the figures for the attempted closure of all wounds which represent the salvage for the Army are the only ones of importance. Chart 10 reveals interesting data in this special field collected from several different hospitals. When 98 per cent of soft tissue wounds healed *per primam* only 60 per cent of all wounds were closed when 90 per cent healed *per primam*.

Based on representative data from various General Hospitals.

90 per cent of all wounds were closed. In the latter hospital, though the healing rate was not so high, the ultimate salvage for restoration to duty was 20 per cent greater.

In the closure of wounds of compound fractures it is again evident that attempts to close wounds should be more universal even if a lower percentage of wounds heal *per primam*; the salvage for future duty is greatly increased when this is practiced.

REASONS FOR IMPROVED STATISTICS

It would be impossible at this time to evaluate and put in proper perspective the reasons why the mortality rates in the United States Army in World War II are one-half as great as those in World War I but there is every reason to believe that the following have each played a rôle.

1. *Resuscitation* The proper treatment of the patient in shock, chiefly by the use of plasma and blood.

2. *Better first aid* by the Company Aid man on the battlefield.

3. *Penicillin and the sulfonamides* which have vastly reduced the horror of infection.

4. *Improved methods of transport and evacuation* which allow earlier meeting of surgeon and casualty and more comfortable travel.

5. *Good general physical condition of the soldier*. This may be partly diet or it may relate to the physical training to which he has been subjected before battle.

THE ORIGIN, FREQUENCY AND SIGNIFICANCE OF MICROSCOPIC CALCULI IN THE KIDNEY

LEO ANDERSON M.D. and JOHN R. McDONALD M.D. Rochester Minnesota

ALTHOUGH considerable interest has been focused on the pathology of the renal pyramid by the studies of Randall and other workers we have been unable to find any published material quoting the exact frequency of microscopic calculi in the pyramids of the kidneys or an adequate description of their origin morphologic characteristics or possible significance. Most of the significant work has been done on the *macroscopic* patches or plaques appearing on the surface epithelium of the pyramid which points into the cavity of the renal pelvis.

We shall therefore define a microscopic calculus as a deposit of calcareous material appearing in the substance of the kidney of a size sufficient to be seen easily under the ordinary low power microscopic lens and measuring at least five to six times the size of the tubular cells.

For the original purposes of this study unselected diseased kidneys removed surgically at the Mayo Clinic provided a basis for the conclusions. Kidneys which had been removed because of tuberculosis pyelonephritis hydronephrosis or stones were studied. As the work progressed it became evident from the findings that grossly normal kidneys removed at necropsy should be included. Accordingly such a group was secured and studied in the same manner.

Careful histologic search was made for microscopic calculi in each pyramid, after the pyramid was cut sectioned stained with hematoxylin and eosin and mounted. Calcareous deposits were sought on the basis of the foregoing definition. When a calculus was found, careful scrutiny as to the possible histogenesis was carried out. If the particular pyramid in one kidney did not show a plaque

further sections from other pyramids of this same kidney were studied in an effort to find such a lesion. This procedure was continued until the calculi were found in each kidney or their absence was shown beyond a reasonable doubt.

Randall noted the microscopic plaques and wrote: "The vast majority of papillary calcium salt deposits have been found to be intra papillary and innocent of further pathologic change."

Vermooten made histologic preparations of the papillae from 103 kidneys which showed the grossly visible plaques on the surface epithelium of the pyramid. He noted the deposition of calcium in the collagen fibrils of the renal papillae in many of the sections but he did not state the exact frequency of this finding.

In 1862 Henle recognized deposition of calcium salt in the renal substance. He termed these deposits calcium infarcts and pictured the lesion as a complete filling of the tubules with chalk.

In 1904 Beer made a macroscopic and microscopic study of 100 kidneys removed at necropsy and concluded that deposits of lime in the kidney were a very common pathologic condition. He stated that lime is found in the tubular epithelium as fine granules. He found the deposits only in the parts of the kidney which he felt were diseased. He spoke of the lime being deposited in fine granules throughout the parenchyma of the kidney. He found calcium deposits in 53 per cent of his 100 cases but never among persons less than 24 years of age.

In 1933 Huggins studied surgically removed kidneys all of which had come to operation because of massive stones. He described deposits of calcium beneath the epithelium of the collecting tubules.

W. Anderson reported on a study of tiny single or multiple deposits of calcium salts in

THE ORIGIN, FREQUENCY AND SIGNIFICANCE OF MICROSCOPIC CALCULI IN THE KIDNEY

LEO ANDERSON M.D. and JOHN R. McDONALD M.D. Rochester, Minnesota

ALTHOUGH considerable interest has been focused on the pathology of the renal pyramid by the studies of Randall and other workers we have been unable to find any published material quoting the exact frequency of microscopic calculi in the pyramids of the kidneys or an adequate description of their origin, morphologic characteristics or possible significance. Most of the significant work has been done on the *macroscopic* patches or plaques appearing on the surface epithelium of the pyramid which points into the cavity of the renal pelvis.

We shall therefore define a microscopic calculus as a deposit of calcareous material appearing in the substance of the kidney of a size sufficient to be seen easily under the ordinary low-power microscopic lens and measuring at least five to six times the size of the tubular cells.

For the original purposes of this study, unselected diseased kidneys removed surgically at the Mayo Clinic provided a basis for the conclusions. Kidneys which had been removed because of tuberculosis, pyelonephritis, hydronephrosis or stones were studied. As the work progressed it became evident from the findings that grossly normal kidneys removed at autopsy should be included. Accordingly, such a group was secured and studied in the same manner.

Careful histologic search was made for microscopic calculi in each pyramid after the pyramid was cut sectioned, stained with hematoxylin and eosin and mounted. Calcareous deposits were sought on the basis of the foregoing definition. When a calculus was found careful scrutiny as to the possible histogenesis was carried out. If the particular pyramid in one kidney did not show a plaque

further sections from other pyramids of this same kidney were studied in an effort to find such a lesion. This procedure was continued until the calculi were found in each kidney or their absence was shown beyond a reasonable doubt.

Randall noted the microscopic plaques and wrote: "The vast majority of papillary calcium salt deposits have been found to be intrapapillary and innocent of further pathologic change."

Vermooten made histologic preparations of the papillae from 103 kidneys which showed the grossly visible plaques on the surface epithelium of the pyramid. He noted the deposition of calcium in the collagen fibrils of the renal papillae in many of the sections but he did not state the exact frequency of this finding.

In 1862 Henle recognized deposition of calcium salt in the renal substance. He termed these deposits calcium infarcts and pictured the lesion as a complete filling of the tubules with chalk.

In 1904 Beer made a macroscopic and microscopic study of 100 kidneys removed at necropsy and concluded that deposits of lime in the kidney were a very common pathologic condition. He stated that lime is found in the tubular epithelium as fine granules. He found the deposits only in the parts of the kidney which he felt were diseased. He spoke of the lime being deposited in fine granules throughout the parenchyma of the kidney. He found calcium deposits in 53 per cent of his 100 cases but never among persons less than 24 years of age.

In 1933 Huggins studied surgically removed kidneys, all of which had come to operation because of massive stones. He described deposits of calcium beneath the epithelium of the collecting tubules.

W. Anderson reported on a study of tiny single or multiple deposits of calcium salts in

the cortex or medulla of the kidneys from 1 500 necropsies. In most of the cases a single section of each kidney was studied microscopically; the section containing a portion of cortex, medulla, and renal papillae. He reported 12 per cent as showing microscopic calcium deposits. He felt that microscopic

calcium was more likely to be deposited in the cortex than in the medulla or papillae.

In 1940 Roscnow reported a study of the kidneys from 209 consecutive necropsies performed at the Mayo Clinic. Particular search was made for the grossly visible patch on the tip of the papillae. He then selected 24 papillae which did not show evidence of gross plaque formation and studied these histologically. Only 4 of the 24 papillae showed intramedullary calcification.

Kjellhede and Lassen examined 135 kidneys removed at necropsy and stated that in 49 of the cases neither macroscopic nor microscopic examination revealed deposits of calcium in or on the papillae.

Posey studied the papillae of 340 kidneys removed at necropsy and noted microscopic deposits of calcium in several of the cases.

ORIGIN OF MICROSCOPIC CALCULI

Calcareous deposits stain bluish black with hematoxylin and eosin. The lesions under discussion are not of sufficient size to require decalcification since they fix and section easily and are visible under the low-power microscope ($\times 100$). Photomicrographs are shown to illustrate the lesions.

Fig. 4. *Amorphous stage.* a, above This microscopic calculus is located just under the epithelium at the tip of the renal pyramid. It is almost completely amorphous, showing none or very little, of the outline of the original droplets. It is situated where it might easily ulcerate through, remain attached and form the nidus on which the supersaturated salts of the urine of the calices might be deposited. $\times 130$. b, The epithelium overlying the calculus has been eroded away and the area is exposed to the urine of the calices. $\times 245$

Since these deposits were not described completely in any of the literature that we read the morphology and apparent developmental cycle of the plaques are outlined in this discussion in some hitherto unused terminology. These terms include flecks of calcareous material, droplets, ingestion stage, coalescing stage and amorphous stage.

Ingestion stage Phagocytic cells which are probably macrophages are abundant about the tubules of the kidney. Kirkman has made an excellent review of the work done on macrophages in the kidney. Phagocytes are shown in Figures 1b and 2b. Bits of blue black staining material can be seen in the cytoplasm of the cells. In Figure 1c and c can be seen flecks of calcareous material which have not yet been ingested by the phagocytes. This may be a result of the cohesion of reabsorbed calcium salts since there is a concentration of calcium about the kidney

Fig. 5. Microscopic calculi in the renal cortex. $\times 130$.

tubules. The ingestion stage refers to the process of ingestion of flecks of calcium by the phagocytic cells which are probably macrophages. This is assumed to be true on the basis of what is demonstrated many times in the sections used in this study such as that shown in Figure 1.

Coalescing stage These droplets of calcareous material clearly coalesce to form plaques. The still remaining borders of the many tiny droplets which went to make up the plaque can be seen still present about the borders of a high percentage of the plaques (Figs. 1a, 2a and 3).

Amorphous stage It appears from the study of many sections that the tiny calculus tends to become amorphous losing the semicircular outline of the original droplets which went to make up the entire plaque. Such a calculus is illustrated in Figure 4a.

Subepithelial calculi Figure 4a shows an amorphous plaque located just under the epithelium at the tip of the renal papilla. This is of the type which Vermooten has suggested may ulcerate through the epithelium and form the nidus for a stone according to Randall's hypothesis of formation of stone.

Figure 4b demonstrates the ulceration of the epithelium by a calculus which originated just under the epithelium. The calculus has ulcerated or eroded away the epithelium thus exposing the plaque to the salts of the urine.

TABLE I.—RESULTS OF THE COMPLETE STUDY ON THE GROSSLY NORMAL AND THE SURGICALLY REMOVED DISEASED KIDNEYS AS TO FREQUENCY OF THE MICROSCOPIC CALCULI

Type of kidney	Kidneys	Average number of sections per kidney studied to prove the presence of the microscopic calculi	Total number of sections made
Pyelonephritic	37	7	
Hydronephritic	26	11	33
Calculous	1	183	18
Tuberculous	24	18	97
Grossly normal	20	166	7
Total	68	244	650

All patients were 9 years of age or more. All kidneys showed the lesions.

Cortical calculi. The cortex of the kidney was not intentionally included in this study but in cutting pyramids the tissue of the cortex was frequently included. The interpretation placed on the finding of the calculi about the glomeruli is that reabsorption of calcium may occur in any part of the tubular system which includes of course the convoluted tubules.

Vermooten expressed the belief that these calcareous deposits occur in the collagen fibers of the renal papilla. With this we would have no argument except to point out that to us they seemed to occur anywhere (Fig. 5) except within the lumen of the tubule. A few specimens were found with the deposits within the tubules but it seemed to us that they had eroded into the tubule from the surrounding parenchyma. Caution must be observed in the interpretation of location since the studies in three planes which would have been afforded with serial sectioning were not used. Figure 3 shows a calculus which is outside the lumen of the tubule but seems to be pressing into the lumen and perhaps in time would have eroded its way into the tubule itself. It would have then been exposed to urine and might have grown to form an interparenchymal stone.

Randall Vermooten and Rosenow have very carefully followed the fate of the plaque after it appears grossly visible while attached to the tip of the renal papilla. That study is not a part of this work. *Macroscopic* plaques which were attached to the tip of the renal

papilla were observed but their frequency was not recorded.

FREQUENCY OF THE DEPOSITS

The results of the study as to frequency of the deposits are shown in Table I. On the average it was necessary to cut and study fewer than 4 histologic preparations on each kidney to prove the presence of the microscopic calculi in all of the kidneys. As many as 10 sections of some kidneys were cut before the lesion was found but in more than 50 per cent of the kidneys the calculi were found in the first section studied. We conclude that these microscopic calculi probably occur in the kidneys of all people above the age of 10 years. Kidneys from the very young were not made a part of this report. The age varied from 9 years to 79 years with a mean of 43 years.

It is interesting to note in passing that the conclusions of this work were arrived at by studying an average of 1/3,333 part of the total pyramid area of each kidney. This figure is easily deduced from the information that each section is only 10 microns (0.001 cm.) in thickness and the knowledge that each kidney contains about 10 pyramids each of which is about 1 centimeter thick. To study all of the papillary area of only one kidney might require as many as 10,000 sections. However this would probably not be necessary in actual practice, since the calculi probably extend over the thickness of many sections.

SIGNIFICANCE

Certain generally accepted postulates regarding the physiology of the kidney will be correlated with the findings of this work in suggesting an interpretation of the causation of kidney stones. These postulates will be defended by references to the work which has been done on physiology and pathology of the kidney.

Postulate 1. The concentration of calcium (and related ions) is high in the tissue fluid about the renal tubules.

Postulate 2. Phagocytic cells occur in abundance about the renal tubules. Most work indicates these to be macrophages. Macrophages have been shown to have a definite affinity for calcium.

Findings (1) Phagocytic cells are demonstrated in the process of ingesting calcium in the renal pyramid (Fig 1b ingestion stage) (2) 'Flecks' of calcium are shown about the renal tubules. These flecks are apparently outside the walls of any cells. (3) Droplets of calcium are shown within the confines of still present phagocytic cell membrane (Fig 1d) (4) Small calcareous plaques are shown about the edge of which can still be seen the rounded borders of the many droplets which went to make up this coalesced deposit (Fig 1a coalescing stage) (5) These microscopic calculi were found in all of the kidneys. The patients were all 9 years of age or more. The lesions were sometimes found in the first section made on a kidney. Sometimes as many as 10 sections were necessary to demonstrate this finding. On an average something more than 3 sections were made on each kidney. Six hundred and twenty nine sections were made of 168 kidneys. (6) Amorphous calculi were found which had entirely lost the outline of the original droplets or cells (Fig 4a amorphous stage) (7) Subepithelial calculi were found which had entirely lost the outline of the original droplets or cells and were located just under the epithelium at the tip of the renal pyramid (Fig 4a) (8) Deposits were found eroding through the epithelium at the tip of the papilla and yet remaining fixed to the papilla (Fig 4b)

Interpretation (1) The study suggests that these microscopic calculi occur in practically all people, as a result of the physiologic process of phagocytic ingestion of the reabsorbed calcium by the kidney tubules. (2) Renal calculus may be a systemic or a dietary disease and not a disease of the kidney *per se*. This assumption follows from the fact that although this tiny calculus which may act as a nidus, is present in practically all people not all people have symptomatic renal calculi. The finding of the tiny calculi in the process of ulcerating through the epithelium at the tip of the renal papilla and yet remaining firmly fixed to the papilla and bathing in the salts of the urine of the calices and receiving deposits therefrom would seem to substantiate the findings of Randall Vermooten and others that these plaques may form the nidus of

renal calculi. This seems especially striking when it is considered that only a small part of the actual pyramidal area of each kidney was actually studied in this work ($1/3$ 333) and yet all kidneys were found to have these tiny microscopic calculi. The answer may lie outside the kidney itself. We may suppose that some substance appears in the urine or blood which acts as a catalyst to the formation of a stone of sufficient size to cause symptoms this catalyst causing the salts of the urine to be precipitated on the aforementioned nidus. Perhaps the unknown substance causes the epithelium to ulcerate thus exposing the plaque to the urine. Really, most microscopic calculi are subepithelial. The formation of symptomatic calculi could be due to the absence of some vitamin like substance or the presence of some other unknown or known substance from the general metabolism of the body or from the diet.

Defense of postulates Postulate 1 is that the concentration of calcium (and related ions) is high in the tissue fluid about the renal tubules. Practically all of the blood supply of the tubular system of the kidney consists of blood which has previously passed through the glomerulus. Cowdry and Shonyo and Mann have made exhaustive studies of the vascular tree of the kidney by the injection corrosion technique and have demonstrated that practically all of the arterial blood reaching the capillaries surrounding the different parts of the tubules is blood which has passed through the glomerulus before it reaches the renal tubules. That there are a few exceptions is not to be denied but that these few exceptions constitute a very small part of the tubular circulation seems also well substantiated. Therefore the *efferent* arterioles of the renal glomerulus carry blood which is soon to pass close to the epithelium of the entire tubular system clear down to the end of the collecting tubules at the tip of the renal papillae.

The function of the glomerulus, it seems well proved by the work of Richards is to filter off by selective osmosis a protein free filtrate of the blood plasma. The constituents of the glomerular filtrate are grouped into three classes (a) high threshold substances which are actively reabsorbed (sodium, po-

tassium calcium magnesium and chlorine) (b) low threshold substances and (c) non threshold substances. For the purposes of this paper we are not interested in the last two classes.

The high threshold substances are in low concentration in the urine and in high concentration in the reabsorbed fluid. This conclusion is drawn from the following reasoning: Richards pipetted off the glomerular filtrate and found that it consisted of a simple protein free filtrate of the blood plasma. As blood passes through the glomerulus, it forms concentrated blood which passes out of the kidney through the efferent arteriole and glomerular filtrate which starts down the tubular system. Two elements of the blood in the first part of the efferent vessels will now be in higher concentration namely the cells and the proteins. The other substances have simply filtered across the osmotic membrane of the glomerulus and remain in the same concentration in the glomerular filtrate as in the blood of the efferent arteriole. The concentration of these ions is therefore unchanged in either. The blood now starts its way down the efferent vessel and passes beside the tubules where the high threshold substances are reabsorbed. Therefore the concentration of these high threshold ions should be high in this blood. Also if the concentration of these easily diffusible ions is the same in tissue fluid as it is in the plasma, the passage of these ions from the glomerular filtrate mentioned previously should increase their concentration in the tissue fluid in the cells and tissues about the tubules as it is reabsorbed. Of course, much of the water is reabsorbed along with the ions but some must go out to form urine. This is estimated to be about 1 cubic centimeter of urine for every 100 cubic centimeters of glomerular filtrate.

Most anatomists and histologists today feel that reabsorption takes place in the convoluted tubules and in the loop of Henle but not down in the tubules of Bellini. Their assumption is largely based on the histologic appearance of the epithelium in the tubules of the collecting type. The epithelium is flattened and undifferentiated in appearance. It does not appear like epithelium elsewhere in

the body which does carry on active reabsorption. However the pyramids contain the lowermost pole of the loop of Henle. As Lowesley and Kirwin stated, "The pyramids are composed of Henle's loops and the straight collecting tubules. We see that reabsorption by the straight collecting tubules is not essential to the completion of the hypothesis and would not be in disagreement with the finding of calcareous plaques well down at the papillary tip. Perhaps the straight tubules do carry on some of the functions of reabsorption."

The question may arise as to the real significance of this supposed high concentration of calcium near the tubules. Some may feel that this concentration is not much higher in actual milligram equivalents than the increase in concentration which occurs with the daily variations of the alkaline tide. Perhaps this is true but it must be pointed out that the concentration of reabsorbed calcium would probably be even higher at this high peak of the day. Perhaps this is exactly the time when the phagocytic cells do absorb the particles of calcium.

Postulate 2 is that phagocytic cells, which seem to be macrophages, occur in abundance about the renal tubules and that macrophages have been shown to have a definite affinity for calcium. A complete review of the subject of macrophages in the kidney is to be found in the work of Kirkman published in 1943. Kirkman also studied the kidneys of rats 25 days of age. The average number of macrophages per square millimeter throughout the pyramid, medulla, and cortex respectively was 53, 93 and 14.

Gersh in 1938 studied the liver and noted that macrophages of the liver as well as those of the spleen had a special affinity for calcium compounds.

Our final interpretation of this study is that in the process of reabsorption of high threshold substances (calcium and related ions) these substances are engulfed by phagocytic cells, which may be macrophages. These ions may first cohere in small masses or "flocks," as shown in Figure 1, before being engulfed by the individual macrophage. Soon the cell contains so much of the metal that it loses its

identity and forms spherical droplets. By cohesive attraction these droplets come together in groups to form a tiny calculus or plaque which we have chosen to call a microscopic calculus. The outlines of the droplets which came together to form the calculus can still be seen about the border of the lesion. Finally all identity of the original droplets is lost in the amorphous plaque. We conclude that this occurs in practically all kidneys. If then these tiny calculi are present in everyone and are found ulcerating through the epithelial membrane of the papillary tip in as high a percentage as is suggested by Randall Vermooten and Rosenow why does not symptomatic renal calculus occur more frequently? We feel that perhaps the inciting factor may lie outside the kidney itself and may be a systemic or a dietary factor.

When this calcareous plaque of the type occurring in almost everyone breaks through the epithelium at the papillary tip it is exposed to the bathing salts of the urine and thus may form a layered concretion or stone which may ultimately break loose and form a symptomatic calculus. That urinary calculi consist predominantly of more than one component is confirmed by Thompson and his associates and by Higgins. This fact lays the foundation for supposing that this microscopic calculus may well serve as the nidus for any type of stone whether it be oxalate urate xanthine cystine carbonate or phosphate when the proper inciting factor comes along.

SUMMARY

A study was made of microscopic calculi as found in the pyramids of 168 kidneys. These included surgically removed kidneys and grossly normal kidneys removed at necropsy. The diseased kidneys were removed for tuberculosis, hydronephrosis, pyelonephritis or stones. Six hundred and twenty nine histologic preparations were made. Originally only one hematoxylin and eosin section of each kidney was studied. Failure to find the microscopic calculi after study of the section from any particular kidney was followed by the cutting and section of further pyramids from the same kidney until the plaques were found or their absence was proved beyond a

reasonable doubt. All of the kidneys were from patients more than 9 years of age. In 50 per cent of the kidneys the plaques were found in the first section studied. In some kidneys as many as 10 histologic preparations were made. The microscopic calculi were found in all of the kidneys.

These microscopic calculi were studied as to morphology and possible histogenesis. It was demonstrated that they were formed by the coalescing of numerous "droplets" of calcareous material. These droplets seemed to be formed by the process of phagocytic ingestion of tiny flecks of black staining material. Attention was directed to the postulate that the concentration of calcium is probably high in the tissue fluid about the renal tubules and to the fact that phagocytic cells occur in abundance about the renal tubules. From these data it was suggested that the calculi were formed by the process of phagocytic ingestion of the calcium which is reabsorbed by the renal tubules.

It was shown that the tiny calculi occur throughout the renal parenchyma. Some were located just under the epithelium at the tip of the papilla and one photomicrograph demonstrated the plaque ulcerating through this epithelium and becoming exposed to the urine of the calices. It is now fairly well accepted that some renal calculi are formed by the process of the salts of the urine being deposited in layers on these plaques. Since a chemically pure calculus is very rare the suggestion is made that perhaps many different types of stone may have this tiny calculus as a nidus.

Since these microscopic calculi occur in practically all people even though only 1/3,333 part of the total pyramidal region of each kidney was cut and examined the question was raised as to why then do not more people form symptomatic stones. The interpretation was suggested that large stones may form only when some inciting factor comes to the kidney which causes the salts to deposit on this eroded nidus plaque. Perhaps this inciting factor substance or catalyst the absence or presence of which is necessary to cause deposition to occur comes from outside the kidney. From the foregoing data the pro-

posal was made that perhaps renal calculus is a systemic or a dietary disease and not a disease of the kidney *per se*

RESECTION OF THE RECTUM WITH RECONSTRUCTION OF CANAL THROUGH THE PERINEAL APPROACH

GORDON MURRAY M.D. F.R.C.S. (Can.) F.R.C.S. (Eng.) Toronto Canada

RESECTION of the rectum with reconstruction is presented as an alternative method of dealing with some lesions of the rectum. The abhorrence of a colostomy by some patients when they are told they have a cancer of the rectum is sufficient to decide them against having operation. The surgeon as well may have some qualms regarding the operation of abdominoperineal resection of the rectum for some reason such as early malignancy, small malignant polypi, ulcers which are of doubtful nature, etc. If a smaller operation without colostomy and good prospects of a return of function would suffice, it would place both the surgeon and patient in a happier frame of mind.

The investigations of Davis and Collier have shown that if a carcinoma of rectum or sigmoid has metastasized beyond the pararectal lymph nodes, the next extension may just as well be in the liver or some remote region as in the next lymph node, namely the intermediate or central groups. Therefore it is reasonable to believe that, if there are no metastases beyond the paracolic lymph nodes, adequate excision of the colon including the primary lesion together with the epicolic and paracolic lymph glands offers almost as good a prognosis for cure as does a wider resection including the intermediate and central lymph nodes.

With that belief in mind, it was considered that in certain selected carcinomas of the rectum, which are not fixed to surrounding structures which are not producing obstruction which have produced no obvious metastases, and which are either a cauliflower or an ulcerative type of lesion involving not more than one-third to one-half of the circumference of the rectum, a local resection and reconstruction might have many advantages.

From the Toronto General Hospital and the Department of Surgery, University of Toronto.

These advantages might be: (1) normal rectal and anal sphincters would be retained with subsequent normal control of the bowels; (2) no colostomy would be required; (3) the shock of operation would be greatly diminished; (4) the danger from infection would be diminished; (5) postoperative complications would be greatly reduced.

A group of patients have been treated in this way and the case reports are presented.

To select the cases suitable for this procedure, it has finally been decided that the ideal case is one in which the growth is above and not involving the sphincters or anal canal mucosa. The growth should be easily palpable through the rectum and for a transanal resection the upper margin of the growth must be palpable with the finger in the rectum and be freely movable on surrounding structures.

OPERATIVE TECHNIQUE

An incision is made from the third spine of the sacrum down to within half an inch of the posterior anal margin. The coccyx, the fifth, and half of the fourth sacral bodies are removed. The pelvic fascia is divided. The dissection is carried around the circumference of the rectum outside the pararectal fascia. When a tape has been placed around the rectum, gentle traction and digital dissection will draw down the upper portion of the rectum and sigmoid. The peritoneum is opened on the anterior surface and sufficient sigmoid is drawn down with which to do a repair with the remaining lower structures of the rectum. When this has been accomplished, the peritoneum is reattached by sutures to the anterior wall of the sigmoid at a new level higher up. The field is then well dusted with sulfathiazole powder and after the field is thoroughly packed off, the rectum is opened well below the growth which is palpable within the lumen. On inspection through this opening, if the growth is not within 1½

Position of patient on table

Line of incision

Fig. 1

Fig. 2

inches of the site of section, the rectum is divided completely across. The sigmoid is divided across well above the growth and this section of rectum with its surrounding para rectal fascia lymph glands, and lymphatics with the contained growth are removed. It is an easy matter then to do an end-to-end suture between the lower end of the divided sigmoid and the upper end of the remaining rectum. The suture material used has been chromic catgut. A single layer of full thickness sutures has been used. Over the posterior surface some supporting sutures in the fat and surrounding structures have also been applied.

A soft drainage tube is passed down to the cavity below the tip of the sacrum. The levatores ani are closed and if some of the fibers of the sphincters of rectum have been divided these are repaired and the skin closed. Digital examination will now demonstrate the suture line surrounding the rectum and a hard rubber tube $\frac{3}{8}$ inch in diameter is passed through the anal canal through the site of anastomosis, and into the proximal segment. This is stitched to the anal margin. No colostomy is required.

There have been no fatalities in this group. The patients stood the operation without shock and within 2 or 3 days were feeling

Fig. 3

MURRAY RESECTION OF RECTUM

Fig. 4.

Fig. 5

CASE REPORTS

quite normal. There has been no peritonitis, or other serious complications. All the patients have had control of the rectum. There has been serous discharge from the sacral drainage in all and in some there has been suppuration with purulent discharge but in most this has healed. There has been no osteomyelitis of the sacrum. There has been no stenosis. In 1 case in which the growth was slightly higher up so that its upper margin could be scarcely felt, there was slightly more tension than is advisable at the suture line. In this case the patient developed a fecal fistula which discharged through the site of the sacral drainage tube for 10 days. It then closed spontaneously without further complications. The patient made an excellent recovery and has normal function of the rectum. In another patient in whom there was a larger growth requiring resection of a greater length of rectum and which probably was not suitable for this procedure, there was a separation of the suture line around half of the circumference of the rectum. A fecal fistula developed and has persisted for 4 months through which a small quantity of feces discharged daily.

What the end may be is not known and a colostomy may be necessary before the condition is cleared up. In half the cases, a temporary fecal fistula developed but this healed spontaneously with 1 exception within 3 weeks. In none of the cases was a colostomy performed.

CASE 1 O M female aged 65 years, was admitted to the hospital March 9 1942. For 3 months this patient had had rectal bleeding. On digital examination her doctor found a small mass $1\frac{3}{4}$ inch in diameter, 3 inches within the rectum. Biopsy showed this to be adenocarcinoma. Three inches of rectum, proximal and distal including the growth were excised and an end-to-end repair carried out. The specimen showed no invasion of regional lymph nodes. The patient was discharged on March 24, 1942. The incision had healed. There was normal control of the rectal sphincter and colon function was normal in all respects.

This patient is still well without signs of recurrence and with normal function now 3 years following the operation.

Fig. 6.

CASE 2 A H. aged 35 years was admitted to the hospital on March 22, 1942. The patient had typical symptoms of carcinoma of rectum which were demonstrated on digital examination. He had lost 30 pounds in weight. There was marked secondary anemia with a hemoglobin of 54 per cent. He was sleeping poorly and was in constant distress from the rectal lesion. A large mass surrounding two-thirds of the circumference of the rectum, ulcerated in its center was easily palpable. It extended downward beneath the mucosa of the anal canal on the posterolateral aspect. The mass was not fixed to surrounding tissues.

Through a sacral approach the rectum was exposed. It was demonstrated on palpation that the mass was extending in the submucosa deep to the external sphincter of rectum. The question arose whether an adequate resection could be carried out locally or whether an abdominoperineal resection would improve the prospects of cure. It was felt, however, with the possible muscle invasion that the prospects for cure under any condition were not good. A local resection was carried out when the posterior half of the rectal and anal sphincters together with rectum and growth were removed. An area of anal mucosa 2 inches by 1 inch was left on the anterior wall. The anal canal was reconstructed and the external sphincter reconstructed around this. The lower end of the sigmoid was anastomosed to the end of anal canal. Microscopic studies demonstrated this growth to be an adenocarcinoma with invasion of regional lymph nodes. The patient made an uninterrupted recovery and left hospital with the incision healed in 3 weeks. There was normal control of the anal and rectal sphincters and the patient had normal colon function.

The patient's general health improved and he returned to work. He returned in 5 months complaining of pain in the region of the left hip. X-ray films at that time showed an area of rarefaction in the femur which had the appearance of a metastatic growth in bone. While the patient continued at work for a year this growth in the femur enlarged until finally there was a pathological fracture. The patient finally succumbed to generalised metastases of peritoneal cavity and skeleton. There was a small local recurrence of the growth in the anal region during the last few months. With local radiation this was controlled and caused no further symptoms.

It is doubtful if a more radical operation would have made any difference to the incidence of metastases as these almost certainly were present before the operation.

CASE 3 J B. aged 70 years, was admitted to the hospital in August 1941. The patient had a malignant polyp 2½ inches in diameter on the posterior wall of the rectum 2 inches from the anal margin.

Through a posterior approach the involved segment of rectum with 2 inches distally and 3 inches proximally was excised together with the

lymphatics and lymph glands. Sulfathiazole was applied and a drainage tube inserted. The skin incision was healed in 10 days. There was no fistula. The suture line in the rectum healed completely without stenosis.

The patient has normal control of the bowel and rectum. Analysis of the specimen showed it to be polypoid adenocarcinoma. There were no metastases in the regional lymph glands removed.

CASE 4 C S. aged 58 years, was admitted to the hospital on September 4, 1942. This patient had an ulcerating carcinoma in the anterior wall of the rectum beginning 1½ inches above the sphincter region. The growth was 2½ inches in length by 1½ inches in width. It moved fairly freely over the vaginal wall anteriorly.

Through the posterior approach the mass with 3 inches of the rectum proximally and 3 inches distally was removed together with the surrounding fat, fascia, lymphatics, and lymph glands. An end-to-end suture was carried out without difficulty. The suture line was completely healed within 3 weeks. There was no fistula. The patient had normal control of bowel and rectum. There was no stenosis on examination. Dissection of the specimen showed this to be an adenocarcinoma with invasion of the epiploic but not of the more remote lymph nodes.

Now 2½ years following the operation there is no evidence of recurrence either locally or generally.

CASE 5 E. T. O. aged 62 years, was admitted to the hospital on October 18, 1943. A malignant polyp 2½ inches in diameter attached to the anterior wall of the rectum was identified. Biopsy described this as a polypoid carcinoma.

Through a posterior approach a length of 6 inches of rectum and lower sigmoid was removed with the surrounding lymphatics and lymph glands with the growth in the center. An end-to-end suture was carried out without difficulty. A drainage tube was passed down to this area. The suture line was completely healed in 2½ weeks. There was no fistula. The patient had normal control of the rectum and bowels. The suture line was healed satisfactorily. There was no stenosis. There was no evidence of recurrence either locally or generally 1½ years following the operation. Sections of the specimen showed no invasion of regional lymph glands.

CASE 6 E. B. aged 72 years, was admitted to the hospital on December 13, 1943. The patient had an adenocarcinomatous ulcer in the posterior wall of the rectum 4 inches from the anal margin. There was no evidence of metastases.

Through a posterior approach the involved segment of rectum with 3 inches of colon proximally and 2 inches distally was removed with surrounding fat, lymphatics, and glands. This was at the upper

margin of the point at which the resection by this method could be carried out. However a satisfactory end-to-end repair was completed although there was somewhat more tension at the suture line than was desirable. The patient developed a fecal fistula which lasted for 10 days at which time it healed. The skin incision was completely healed in 3 weeks. The patient had normal control of bowel and rectum. There was no stenosis and no evidence of new growth 1 year following the operation. Anal vs. showed this to be adenocarcinoma involving the muscular coats and with no invasion of regional lymph glands.

CASE 7. A. D., aged 60 years was admitted to the hospital on January 7, 1944. This patient had symptoms typical of carcinoma in the rectum. On examination there was an ulcerated area on the posterior wall, the growth measuring 3.5 centimeters in diameter. It was freely movable and it was thought that it was suitable for a local resection.

Through a posterior approach the rectum with the pararectal fascia, lymphatics and adjacent lymph glands was dissected free. Seven inches of the lower sigmoid and rectum was removed with the malignant mass in its center. An end-to-end suture was carried out without difficulty giving a satisfactory repair. Sections of the specimen showed it to be an adenocarcinoma with metastases in the pararectal lymphatics but none in the immediate lymph glands which were removed. The incision was healed completely in 2 weeks. There was no fistula.

To date there is no evidence of recurrence. The patient has normal function of the bowels and control of the rectum.

CASE 8. A. O. G. aged 52 years was admitted to the hospital on June 7, 1944. The patient had a malignant ulcer on the posterior wall of the rectum $4\frac{1}{2}$ inches from the anal margin.

Through a posterior approach the involved segment with $2\frac{1}{2}$ inches proximal and $2\frac{1}{2}$ inches distal was removed. An end-to-end suture was carried out satisfactorily. The posterior incision was healed completely in 2 weeks. There was no evidence of fistula. The bowels and rectum were functioning normally. Analysis of the specimen showed this to be only a chronic ulcer which differed from the original hypothesis. There was no evidence of malignancy. There was no primary or invasion in the regional lymph glands.

CASE 9. A. N. aged 58 years, was admitted to the hospital on August 11, 1944. The patient had an ulcerated carcinoma in the posterior wall of the rectum 3 inches above the anal margin. It was lightly attached to surrounding structures, especially on the right posterolateral quadrant. There was no evidence of metastases elsewhere.

Through a posterior approach the involved segment of the growth with 2 inches proximally and 3 inches distally was removed. A satisfactory end-to-end repair was carried out. However there was more tension in the suture line in this case than was

desirable. Sulfathiazole was applied and a drainage tube was passed down to the site. The patient developed a fecal fistula on the eighth day which discharged a moderate amount of feces through the upper end of the incision. In the meantime the bowels were functioning naturally. On palpation through the rectum the posterior half of the suture line had separated leaving a gap of $1\frac{1}{2}$ inches between these margins. The fistula continued to discharge small quantities of feces. Otherwise there was normal control of the bowels.

Now 7 months following the operation there is still a small fecal fistula over which the patient wears a small layer of gauze. Otherwise the bowels are functioning normally. The patient's general health is excellent. There is no evidence of recurrence of the growth. Analysis of the specimen showed this to be adenocarcinoma. The glands removed from the perirectal area showed only chronic lymphadenitis with no evidence of new growth.

CASE 10. M. M. aged 62 years, was admitted to the hospital on August 11, 1944. The patient had a carcinomatous ulcer $2\frac{1}{2}$ inches in diameter in the posterior wall of the rectum 3 inches above the anal margin. It was fairly freely movable but still it was felt that there was slight attachment to the surrounding structures, especially on the left posterolateral region. There were no evidences of metastases elsewhere.

Through a posterior approach the involved segment of rectum with 3 inches proximally and 2 inches distally was removed. The surrounding fat, lymphatics and lymph glands were removed. A satisfactory end-to-end repair was carried out. Sulfathiazole was used as in all these operations, and a drainage tube was passed down to the site. The incision was completely healed in $2\frac{1}{2}$ weeks. There was no fistula at any time. The patient had normal control of bowel and rectum. There was no stenosis on digital examination. The analysis showed this to be an adenocarcinoma. The regional lymph glands in the pararectal position showed no invasion by carcinoma.

CASE 11. T. F. aged 64 years was admitted to the hospital in August 1944. This patient had a polypoid carcinoma on the posterior wall of the rectum 4 inches from the anal margin. There was no evidence of fixation of the growth.

Through a posterior approach the affected segment with the growth with $3\frac{1}{2}$ inches proximally and $2\frac{1}{2}$ inches distally was removed. A satisfactory end-to-end repair was carried out. At no time was there a fistula. The incision was healed in 10 days. The patient had normal control of bowel and rectum. There was no stenosis. The analysis of the specimen showed this to be an adenocarcinoma. There was no

evidence of invasion of regional lymph glands.

CASE 12. M. T. aged 21 years, was admitted to the hospital on October 10, 1944. The patient had symptoms leading to the diagnosis of rectal polyp. On biopsy this was shown to be a malignant polyp on the posterior wall of the rectum within an inch of the anal mucosa. This growth was treated in the radiology department by deep therapy and interstitial radium application. The lesion appeared to be cured by this procedure. However, it left the patient with a radiation ulcer $1\frac{3}{4}$ inches long and $\frac{3}{4}$ inch wide in the posterior wall of the rectum extending down into the region of the sphincter posteriorly. As this had persisted for a year and a half and was causing a great deal of discomfort and disability it was suggested that an excision of this area be carried out.

On October 10, 1944 the area was exposed through a posterior incision. The circumference of the rectum was defined and the area of ulceration localized. The posterior two-thirds of the circumference of the rectum was excised by an elliptical incision including the ulcer. This was repaired with a double line of sutures. A drainage tube was passed down to this site after applying sulfathiazole crystals. Healing was quite satisfactory and was completely closed in 3 $\frac{1}{2}$ weeks. The symptoms were entirely relieved. On rectal examination the suture line was palpable. It was well healed.

CASE 13. I. W. aged 55 years was admitted to the hospital on November 13, 1944. This patient was demonstrated 6 months previously to have carcinoma of the rectum. It was adherent to surrounding structures. It was treated by the radiologists with deep therapy and with interstitial radium. The growth diminished in size leaving only a scarred area causing fairly severe stenosis 3 inches above the anal margin. He was seen in consultation with the radiologists when it was decided to make an attempt to resect this segment of the invaded rectum.

Through a posterior approach it was demonstrated that there was much more scarring in the tissue surrounding the rectum than was found under ordinary conditions, probably as a result of the radiation therapy. However it was not difficult to define a plane through which a dissection could be carried out surrounding the rectum, pararectal fascia, lymphatics and adjacent lymph nodes. The involved segment of rectum with $2\frac{3}{4}$ inches proximally and 1 inch distally was removed. An end-to-end suture was carried out without difficulty. The incision was somewhat slower in healing. This might have been the result of the previous radiation. However it was healed satisfactorily in 4 $\frac{1}{2}$ weeks. A fistula discharging only a small quantity of feces developed for a period of 3 weeks. This finally closed. The patient had normal control of bowel and rectum and there were no symptoms. The analysis of the specimen removed showed that there were still carcinoma cells in the region imbedded in massive scar tissue. The lymph glands removed with the rectum showed no invasion by carcinoma.

CASE 14. G. T. B. was admitted to the hospital in March 1945. This patient clinically had carcinoma palpable with the tip of the finger on the anterior wall of the rectum. It was felt to be moderately large and probably not very suitable for a perineal excision. However as the patient was firmly decided against having a colostomy it was decided to attempt removal by the perineal approach.

At the operation it was found that the mass was fairly large, although there was no extension to lymph glands beyond the regional group which could be identified at operation. The mass was removed. The repair was carried out without much tension. A tube was passed through the anastomosis and post sacral drainage provided. The patient stood the operation very well. The incision healed without infection. There was a slight fecal discharge for about 1 week. By the end of 3 $\frac{1}{2}$ weeks the incision and the fistula were completely healed. The patient had complete control of the sphincter at that time. There was no stenosis present at the suture line and the patient made a satisfactory recovery.

The pathologist's analysis of the specimen showed this to be an adenocarcinoma of colon. The regional lymph glands showed no invasion by secondary growth. They showed only chronic lymphadenitis.

CASE 15. C. C. aged 64 years, was admitted to the hospital in May 1945. In 1931 this patient had had an operation for internal hemorrhoids at another hospital. A polypoid mass $1\frac{3}{4}$ by $1\frac{1}{4}$ inches was removed. On section this was demonstrated by the pathologist at that time to be adenocarcinoma. The patient was quite free from symptoms until January 1945, at which time he began to have symptoms typical of carcinoma of rectum. On examination there was a polypoid mass which was situated in a position on the anterior and left lateral wall of the rectum where it could be palpated with the finger freely but its upper margin could not be felt easily. There was one unpleasant symptom which was irritation of the bladder making one doubt if this growth were resectable. It was decided to attempt an exploration through the perineum being prepared to continue to do an abdominal stage if the growth were not removable through the former route. It was found that the growth could be quite freely detached from all the surrounding structures. It was brought down into the post sacral incision without difficulty. It was resected and a satisfactory end-to-end repair was carried out without colostomy. The patient made an untroubled recovery. There was a fistula present for about 3 weeks. This healed and left the patient with a normal functioning rectum without any stenosis.

The pathologist's analysis of the specimen showed an adenocarcinoma of fairly large proportions of the cauliflower type but no invasion of regional lymph glands.

CONCLUSIONS

1 In early carcinoma of rectum extending as low as the anal canal, resection with reconstruction and preservation of the sphincters without colostomy is a satisfactory procedure

2 The operation is attended by very little shock or hemorrhage. The patients all made a satisfactory recovery. There were no deaths in this group reported

3 This report is based on 15 cases. With the exception of 2 cases all infection in the perineal wound had healed and signs of fistula had disappeared within 3 weeks. In one of the remaining two the fistula closed in 5 weeks. In one other it was present at 4 months. What the end result in this will be is not yet determined. The prospects for cure in this group seemed fairly satisfactory. This was based on the pathologist's evidence that there was no extension of the growth beyond the local lesion with possible infiltration of the surrounding muscular wall. There was 1

lymph gland invasion. All the patients had normal control of sphincters. There was no stenosis at the site of anastomosis. The rectum function was normal in all respects

4 One patient has died from recurrent growth with metastases in the peritoneum and bone causing a fracture of femur. This case Case 2 in this series was an unsuitable case as it was a very advanced carcinoma with invasion of the anal mucosa and surrounding structures. It is quite obvious however that any other type of procedure would not have offered any better prospects for cure

STUDIES ON EXOPHTHALMOS PRODUCED BY THYROTROPIC HORMONE

I A Study of Exophthalmos Produced by Various Thyrotropic Hormones and the Influence of the Testes on the Exophthalmos

BROWN M. DOBYNS M.D., Rochester Minnesota

MANY investigators have demonstrated that thyrotropic hormone from the anterior pituitary may be used to produce exophthalmos in guinea pigs. Many of the observers have found that the exophthalmos was produced more easily in thyroidectomized than in intact animals. The problem of obtaining accurate measurements of the prominence of the eyes in many of these experiments has been a major obstacle. Two improved methods for measuring minute changes in the prominence of the eyes have been devised and described elsewhere (6).

Using these two methods of measuring exophthalmos, a rather extensive investigation has been undertaken, first, to compare the changes in the prominence of the eyes induced by various preparations of thyrotropic hormone and second, to correlate the exophthalmos with the various tissue changes which occurred as a result of administration of the hormone. This report not only describes the effects induced by the administration of various anterior pituitary preparations on the prominence of the eyes in guinea pigs but also takes into consideration the influence of the testes on the development of exophthalmos.

The literature dealing with the relation of the gonads to exophthalmos is confusing because of the variety of ways which have been employed to produce exophthalmos. Marine (16-18) and Marine and Rosen (20) reported that exophthalmos did not develop in gonadectomized puberal rabbits as it did in normal animals when thyroid insufficiency was pro-

duced by thyroidectomy or methyl cyanide. They (17-21) found that the production of permanent cryptorchism with the associated degeneration and absorption of germinal epithelium of the testes did not inhibit this type of exophthalmos in rabbits. Spontaneously exophthalmic guinea pigs did not show a regression of their exophthalmos after gonadectomy. They reported (21) that these types of exophthalmos could be instantly converted to enophthalmos by cervical sympathectomy. This fact would serve to distinguish this type of exophthalmos from that produced by thyrotropic hormone, which is not influenced by cervical sympathectomy (32-33-36). No changes in body weight of the animals resulting from surgical procedures were described.

Smelser (33) reporting studies on exophthalmos induced by thyrotropic hormone referred to the fact that some of his male and female animals were gonadectomized. Special reference, however to the results in these animals was not included. Smelser (38) reported that oophorectomy had no effect on the changes that were induced by thyrotropic hormone in the Harderian glands of guinea pigs.

Marine (17-18) reported that sex hormones such as testosterone propionate, androsterone and dehydroandrosterone caused a return of the exophthalmos previously abolished by orchectomy.

I described in an earlier publication (6) the increase in the prominence of the eyes after thyroidectomy in normal guinea pigs. In the preliminary experiments of this investigation, it was found that after thyroidectomy had been performed, preparatory to the administration of thyrotropic hormone, the eyes increased in prominence. That series of observa-

Abklyment of thesis submitted by Dr. Dobyns to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Ph.D. in Surgery. The work on which the thesis was based was done in the Division of Experimental Medicine of the Mayo Foundation in the laboratory of Dr. George M. Huggins.

Dr. Dobyns, Fellow in Surgery Mayo Foundation.

Fig. 1. Changes of the prominence of the eyes resulting from thyroidectomy in the normal guinea pig. The increase in the width of the frontal bones, as illustrated in the lower right, is represented by the same scale as the measurements dealing with the eyes.

tions on the effects of thyroidectomy alone served as a control for the experiments to be described dealing with the effects of thyrotropic hormone.

The control experiment is very briefly reviewed and illustrated. Seventeen growing male guinea pigs weighing from 322 to 500 grams were used. Thirteen were thyroidectomized and 4 served as controls. The intercorneal distance and body weight of these animals were determined at intervals of from 1 to 3 days for 14 to 26 days. It can be seen in Figure 1 that thyroidectomy alone causes some increases of the prominence of the eyes.

EXPERIMENTAL METHOD

The following anterior pituitary products were used in these experiments (1) antuitrin T prepared for clinical investigation (2) purified thyrotropic factor prepared for clinical investigation (3) a crude thyrotropic preparation from the anterior pituitary of swine prepared especially for this study and known to contain small amounts of other known im-

purities and (4) the specific metabolic principle of the pituitary which was prepared according to the specifications of Collip and his co-workers (3, 5).

Normal guinea pigs weighing between 300 and 400 grams were selected from our Institutional stock colony. Animals showing any spontaneous exophthalmos or retardation of growth were avoided. Since color affords greater facility in obtaining accurate measurements (6) animals which possessed white cream or buff color about the face, which possessed a darkly pigmented face, were selected for study. The animals were maintained on standard laboratory ration consisting of oats, alfalfa hay, beets and lettuce or green grass as the season permitted.

The intercorneal distance was measured three times with each of the two eyes at intervals of 1 to 3 days. The average of 6 determinations represented the protrusion of the eyes for that particular day. Body weight was likewise recorded. The animals were thyroidectomized and, after varying

Fig. The gross appearance of exophthalmos produced by antuitrin T (Parke, Davis and Co.) a, left, Normal guinea pig; b, thyroidectomized guinea pig treated with antuitrin T.

were given one of the thyrotropic preparations at daily intervals. Approximately half of the animals in some of the groups observed were not only thyroidectomized but also orchiectomized.

At the conclusion of these observations, the animals were killed and the tissues were studied grossly and microscopically with a variety of staining techniques. The results of the tissue observations will form the basis for subsequent reports.

A. THE EFFECT OF ANTUITRIN T ON THE PROMINENCE OF THE EYES IN THE GUINEA PIG

Method. Data assembled from 19 animals comprise the basis of the report on this thyrotropic product. Eight animals were thyroidectomized. Seven were thyroidectomized and orchiectomized. Four were normal and served as controls. Five to 11 days were allowed to elapse between the operation and the beginning of administration of antuitrin T except that in 2 cases, in which the animals were both thyroidectomized and orchiectomized 31 days elapsed before the administration of the hormone was begun. The animals received by either the intraperitoneal or the

subcutaneous route, 0.5 cubic centimeter (1.0 c.c. in 1 case) of antuitrin T containing 25 Junkmann-Schoeller units¹ each day for 3 to 32 days.

Antuitrin T when given in this amount (0.5 c.c. daily) was found to produce a rather toxic effect on many of the animals. For this reason its administration was on rare occasions discontinued for a day in order to permit the animal to regain its strength.

Because the literature contains controversial opinions concerning the relations of vitamin C to the effects caused by thyrotropic hormone and because these animals were studied during the winter months, when guinea pigs are often on the border line of scurvy, some data were assembled on the effects of giving vitamin C. Accordingly 5 animals were given 2.5 milligrams and 2 were given 5 milligrams of crystalline ascorbic acid daily intraperitoneally during the time they received antuitrin T. Ascorbic acid however failed to influence in any way the exophthalmos that developed.

¹That amount of extract which when injected daily for 3 days into guinea pigs weighing 200 to 300 grams causes a perceptible hypertrophy of the epithelium and disappearance of colloid in the thyroid of 3 animals (11, 1).

Fig. 3. The changes in body weight and intercorneal distance in animals receiving antuitrin T illustrated by the records of representative animals. Arrows indicate daily injection of antuitrin T a, above, Thyroidectomy—gonads intact—slight loss of body weight b left, below thyroid-

ectomy—gonads intact—extreme loss of body weight. (Extremes in influence of body weight are shown by a and b. Influence of loss of body weight on intercorneal distance is easily seen. Compare with Fig. 4 showing loss of body weight by fasting.) c, Thyroidectomy and gonadectomy

Results Within 30 minutes to 1 hour after the injection of antuitrin T many of the animals appeared ill. Their state was characterized by inactivity and a ruffled coat. In 12 to 24 hours some animals demonstrated stiffness of the limbs which in some instances almost amounted to a state of cataplexis.

Definite gross exophthalmos occurred in most of the animals in spite of considerable loss of weight (Fig. 2). The greatest actual increase in intercorneal distance was 3.5 mill-

imeters. Although thyroidectomy *per se* resulted in a protrusion of the eyes, the increase produced by antuitrin T was superimposed in a much more acute and striking fashion (Compare Fig. 1 with Fig. 3a and c.) With both of the methods of measurement employed there was obtained in most instances an unequivocal increase of intercorneal distance within 24 hours after injection.

The removal of the testes had no inhibitory effect on the development of exophthalmos

^aTreatment given on 7 of 8 days
(Treatment given on 8 of 9 days)

(Fig. 3c and Table I) As a matter of fact the two most striking degrees of exophthalmos occurred in animals which had been orchectomized.

Control experiments It is common knowledge that when an animal loses weight there is a recession of the globes of the eyes into the orbits. Because some of these animals lost rather striking amounts of body weight (Fig. 3b) further observations on the relation of changes in the body weight to changes in the prominence of the eyes were indicated. Furthermore, it was necessary to know whether the solvent in which the active principle of antuitrin T was dissolved or the preservative present in the solution could cause exophthalmos or the toxic effects observed in these animals.

When the solvent¹ including the preservative but without the pituitary ingredient,

was given in comparable amounts to 6 control animals there were no increases in the intercorneal distances nor were there evidences of a toxic influence, such as hitherto observed.

In a second control experiment the changes in the intercorneal distance were studied in animals whose body weights were decreased by fasting. Food was withheld from 5 animals comparable to those used in the preceding experiment but drinking water was provided *ad libitum*. These animals lost from 30 to 40 per cent of their body weight in 10 to 16 days. Their body weights and the changes in their intercorneal distances were recorded at frequent intervals. As the retrobulbar tissue became depleted concurrently with atrophy of comparable tissue elsewhere in the body the globes of the eyes receded into the orbit. The correlation between the regression in the prominence of the eyes and the decrease in body weight is illustrated by a representative animal of this group (Fig. 4). This illustration shows that for the first 40 grams of loss in body weight in an animal of this size there was a decrease in intercorneal distance equal to the amount *a*. For an additional loss of 40 grams of body weight an added regression equal to the distance *b* resulted and so on.

On the basis of these correlations between decreases in weights of body and regressions of eyes, correction factors have been devised for use in the interpretation of the eye measurements assembled from animals which had been treated with antuitrin T and had lost weight. An animal which lost considerable weight when antuitrin T was administered is illustrated (Fig. 3b). Although the prominence of the eyes in this animal (Fig. 3b) increased relatively little, there was an exophthalmos-producing mechanism which prevented a regression of its eyes such as occurred in the fasting animal which lost a comparable amount of weight (Fig. 4). With the application of the correction factors it has been possible to evaluate the exophthalmos-producing effect of antuitrin T more accurately thus correcting for the loss of tissue volume in the orbit associated with loss of weight. Table I has been compiled in this way.

It will be seen that 3 of the 19 animals sustained a slight decrease of the prominence of

¹The information necessary for the preparation of the solvent for antuitrin T was obtained from the manufacturer.

the eyes while receiving antuitrin T. The decrease, however, was not of the magnitude of that sustained by a fasting animal losing the same amount of weight. On the other hand, some animals showed considerable increase in the prominence of the eyes in spite of considerable loss of body weight. After a correction of the exophthalmos based on the loss of body weight it can be seen (Table I) that the exophthalmos produced in gonadectomized animals was as great as that in animals with testes intact. Except for 2 animals which were orchectomized and in which more striking exophthalmos developed, the 2 groups of animals were essentially equal in this regard.

In the 4 intact animals which received antuitrin T, there did not develop a degree of exophthalmos comparable to that of the thyroidectomized animals even though correction for losses of body weight was made. Thus difference may be explained at least in part by the data derived from control experiments which illustrated how thyroidectomy alone produced some increase of the prominence of the eyes.

Comment The importance of accurately correlating changes in body weight with changes in the prominence of the eyes is clearly illustrated. Loeh and Friedman and also Smelser (32-34) recognized a regression of exophthalmos in animals which lost considerable weight. It is common knowledge that exogenous origin, will cause a loss of body weight. Whether of endogenous or of exogenous origin, whether of thyroidectomized animals or of animals which lost weight by other means, many authors have reported that exophthalmos was produced less readily in intact animals than in thyroidectomized animals. Absence of the thyroid presumably precludes the possibility of thyrotoxicosis developing when thyrotropic hormone is given. It has been pointed out by Marine (18) in intact animals and Smelser (34) in thyroidectomized animals that thyroxine when administered to animals simultaneously with thyrotropic hormone diminishes the exophthalmos. It has also been shown that after the administration of thyrotropic hormone to normal animals for several weeks the incidence of exophthalmos increases considerably. Friedgood (8) has shown that this latent exophthalmos develops later when the thyroid of the animal has become refrac-

Fig. 4. The changes of body weight and intercorneal distance in a fasted animal. *a*, The decrease in the prominence of the eyes coincident with the first 40 gram loss of body weight. *b*, The decrease in the prominence of the eyes coincident with the second 40 gram loss of body weight. *c*, The decrease in the prominence of the eyes coincident with the third 40 gram loss of body weight. *d*, The decrease in the prominence of the eyes coincident with the fourth 40 gram loss of body weight. (Compare with Fig. 3a, b and c.)

tory to the influence of thyrotropic hormone. When this phase is reached the basal metabolic rate falls, evidence of thyrotoxicosis disappears and the animal usually gains weight. At this time the prominence of the eyes would be expected to increase.

These experiments reported here which correlate fluctuation of body weight with changes in the prominence of the eyes contribute to our understanding of some of the differences in interpretation of exophthalmos which have appeared in the literature.

B THE EFFECT OF A PURIFIED THYROTROPIC FACTOR (ARMOUR¹) ON THE PROMINENCE OF THE EYES IN GUINEA PIGS

Method This product was administered in 0.5 and in 1 cubic centimeter (in one instance 2 c.c.) daily amounts to 8 male guinea pigs. Six of these animals had been thyroidectomized.

¹ Assayed and found to contain 5 Rowlands-Parkes units per cubic centimeter according to the manufacturer's method. One Rowlands-Parkes unit is that amount which when injected daily for 5 days into a 100 gram female guinea pig will cause the thyroid to double its weight or attain a weight of 66 milligrams (8).

↑ = 1 cc. daily dosage purified thyrotropic factor

Fig. 5. Changes of intercorneal distance and body weight in a thyroidectomized guinea pig receiving purified thyrotropic hormone. The increase of intercorneal distance is comparable to the increase caused by thyroidectomy alone. (Compare with Fig. 1)

mixed. One of these had also been orchectomized. Two others were subtotally thyroidectomized. The administration of this so called purified thyrotropic factor was begun 2 to 4 days after thyroidectomy except for one animal, which began to receive 2 cubic centimeters of the preparation on the 16th post

operative day. All animals received the product for periods ranging from 7 to 39 days.

Results In contrast to antultrin T this "purified" thyrotropic product in the amount given did not cause a loss of body weight nor did it cause the toxic manifestations previously described. Furthermore it did not produce very definite evidence of exophthalmos (Fig. 5). It would appear that the increase of the prominence of the eyes in these animals occurred in a manner comparable to that seen in growing animals which had been thyroidectomized alone (compare Fig. 1 and Fig. 5). In view of the weight which was gained, the increase of intercorneal distance certainly is not striking (Table II). Two animals, however obtained an increase which was out of proportion to the changes in body weight. Demonstrable differences in the effects due to the different doses administered were not evident for one animal which received 2 cubic centimeters (containing 10 Rowlands-Parkes units) daily described no appreciable change in the intercorneal distance, further evidence that this pituitary thyrotropic preparation in the amounts given had relatively little or no exophthalmos-producing effect.

Fig. 6. Changes of intercorneal distance, body weight and food consumption in a thyroidectomized animal receiving crude pituitary thyrotropic factor. Thyroidectomy was performed 3 days before administration of the crude thyrotropic preparation was begun. Arrows indicate injection of 20 milligrams of the product.

C. THE EFFECT OF A CRUDE PITUITARY THYROTROPIC PREPARATION¹ ON THE PROMINENCE OF THE EYES IN GUINEA PIGS

Because the 'purified' thyrotropic factor caused hyperplasia of the epithelium of the thyroid but did not induce appreciable exophthalmos, the question arose whether in the process of 'purification' the product may have lost its exophthalmos-producing quality. Some investigators have suggested the possibility that the anterior pituitary may contain two factors, one of which causes exophthalmos and the other thyroid hyperplasia.

A crude thyrotropic preparation was made from the anterior pituitaries of swine in a manner comparable to that employed in preparing the 'purified' thyrotropic factor except for the efforts at purification. This product was reported by the manufacturer to contain some adrenotropic and some gonadotropic principles in very minute quantities.

Method. Ten animals were used in this study. Six of the 10 animals were thyroidectomized and 4 were thyroidectomized and

orchiectomized. Three to 10 days after thyroidectomy daily administration of 20 milligrams of the powdered crude thyrotropic preparation suspended in water was begun. After 6 days of this administration the amount was increased to 40 milligrams in half of the animals. This however caused very little if any added effect on the exophthalmos that already had been produced by the smaller amount.

Before this crude thyrotropic product was given 2 of the animals received each day for 5 days, 1 cubic centimeter of the so called purified thyrotropic factor bearing the same lot number as that used in the preceding experiment. Since these injections proved ineffective in producing exophthalmos the administration of the crude preparation in the same unit dose was begun. The changes in body weights and in intercorneal distances were observed at frequent intervals as previously described. In addition the consumption of food was carefully determined.

Results. On administration of this crude thyrotropic preparation the animals were less lively than normal but there was no profound change in the animals' appearance or in their

¹Kindly prepared by the manufacturer for this experiment under the direction of Dr. F. Frey, and assayed and found to contain 3 International Units per 4 milligrams of powdered extract. See preceding foot note for definition of unit.

*Thyroidectomy
 †Thyroidectomy and gonadectomy
 ‡The width of the (frontal) bones increased 5 mm. in each of these animals, an observation which explains in part the decrease of exophthalmos.

activities such as seen in animals receiving antuitrin T.

The food intake paralleled the changes of body weight (Fig. 6). Instead of losing weight as did the animals receiving antuitrin T these, for the most part, gained slightly. Two of the animals receiving the product for a longer time than the other animals gained considerable weight. In these 2 instances, the increase in intercorneal distance was due in part to the growth of the skull, for in these 2 animals the width of the frontal bones between the orbits increased 0.5 millimeter.¹

The exophthalmos produced by the amounts of this crude product given was not as striking as that produced by antuitrin T although the eye changes were grossly evident (Fig. 6 Table III). Previous orchectomy had no apparent inhibitory effect on the exophthalmos.

Although bio-assays, in Rowlands-Parkes units, of the crude and 'purified' products indicated that the amounts of thyroid-stimulating substance given were comparable, yet exophthalmos resulted only in animals which received the crude preparation. The difference in the exophthalmos-producing effect of the 'purified' and crude products is further illus-

trated by the prompt increase in the intercorneal distance of the two animals previously mentioned, which took place when the crude product was given although the animals had just previously failed to respond to the 'purified' product.

D. THE EFFECT OF THE SPECIFIC METABOLIC PRINCIPLE² ON THE PROMINENCE OF THE EYES OF GUINEA PIGS

In the two preceding experiments, it was found that a crude product produced both thyroid hyperplasia and exophthalmos. On the other hand, a so called purified product, which produced thyroid hyperplasia to the same degree failed to induce exophthalmos. The question arises whether in the process of purification an exophthalmos-producing substance may have been lost. This prompted an effort to find a substance which would produce exophthalmos but would not produce thyroid hyperplasia.

Billingsley, O. Donovan and Collip (3) separated a thyrotropic preparation into two fractions. The thyroid-stimulating fraction raised the basal metabolic rate over a period of a number of days by its stimulating effect on the thyroid. The other fraction, known as the specific metabolic principle, caused an elevation of the basal metabolic rate within several hours but did not induce hyperplasia of the thyroid.

Since antuitrin T induced a loss of body weight and a striking exophthalmos while the other products in the amounts given were less effective in these respects, a study of the exophthalmos-producing effect of the specific metabolic principle was undertaken.

Method and results. The specific metabolic principle was administered to 4 thyroidectomized guinea pigs. The previously described methods of observation were used. On the 3rd postoperative day the daily administration of 1 cubic centimeter of this product to 3 animals was begun. After 2 injections had been given and 48 hours had elapsed, there was no definitely demonstrable increase in the intercorneal distance in any of the 3 animals. The daily administration was then increased

¹This product conformed to the specifications described by its discoverers (3, 4).

²The method of control of skull growth is described elsewhere. (5)

to 2 cubic centimeters and the larger amounts also were given to a 4th animal. After 7 to 9 days there was still no evidence of an exophthalmos-producing effect from this product. It was noted that in the 2 animals in which a little more than 1 millimeter increase of intercorneal distance developed most of this increase occurred after thyroidectomy and before the administration of the specific metabolic principle. Data on this experiment are given in Table IV.

SUMMARY

The exophthalmos-producing effect of several different preparations of thyrotropic hormone has been studied. In addition the effect of the presence or absence of the testes and thyroid on the development of exophthalmos was observed. The gradual changes in the prominence of the eyes of guinea pigs have been observed by two improved methods of measurement which were used at frequent intervals.

It was found that 25 Junkmann Schoeller units daily of antuitrin T caused toxic manifestations, a loss of weight and a striking degree of exophthalmos in thyroidectomized as well as normal animals. A so called purified thyrotropic preparation given in quantities of 25, 50 and 100 Rowlands-Parkes units daily did not produce appreciable exophthalmos nor toxic manifestations in the thyroidectomized animals but did cause hyperplasia of the epithelium of the thyroid in intact animals. A crude thyrotropic product, given in the same concentration in terms of thyroid stimulating effect as the "purified" preparation produced exophthalmos and slight toxic manifestations in thyroidectomized animals as well as hyperplasia of the epithelium of the thyroid of intact animals.

In many instances the development of exophthalmos was recognizable within 24 hours after the administration of antuitrin T.

Because loss of body weight is usually associated with a regression of eyes and because many of the animals receiving antuitrin T lost weight, control observations were made on the regression of the prominence of the eyes of animals that were caused to lose weight by fasting. These observations contributed much to the interpretation of changes in the prom-

7	+23	5	5
7	+45	5	5
9	-27		50

inence of the eyes of animals that lost comparable amounts of body weight because of the effects of some of the thyrotropic products. A correction for the loss of weight and consequent change in the eyes in thyrotoxic animals indicated that the exophthalmos-producing quality of thyrotropic hormone was less effective in intact animals than in thyroidectomized animals. This difference was thought to be due to the superimposed exophthalmos-producing effect of thyroidectomy alone (6).

Because the specific metabolic principle raises the basal metabolic rate but fails to stimulate the thyroid and because it is a fraction of thyrotropic hormone preparations it was investigated for exophthalmos-producing qualities. This principle did not produce exophthalmos.

Approximately half of each group of animals that were studied were orchectomized. It was found that orchectomy had no inhibitory effect on the exophthalmos produced by thyrotropic hormone.

MASSIVE ISLET CELL TUMOR OF THE PANCREAS WITHOUT HYPOGLYCEMIA

SEATON SAILER, M D and M. M ZINNINGER M D F A C S., Cincinnati Ohio

NEOPLASMS of the pancreatic islet tissue are usually recognized clinically by their ability to produce hypoglycemia with vasomotor and central nervous system manifestations. The islet cell tumor need not be of large size to produce symptoms of hyperinsulinism and indeed it is unusual to find one of considerable bulk that fails to exert an appreciable physiologic effect. The great majority of these tumors are composed histologically of mixed alpha and beta cells or exclusively beta type cells and exhibit distinct secretory granules in their cytoplasm. In most instances growth is benign. A number of questionable and a few undoubted malignant cases have recently been carefully tabulated and discussed (1-4).

The case under consideration appears unique in that it concerns a patient harboring a singularly large islet cell pancreatic tumor without clinical or biochemical evidence of hyperinsulinemia. Histological study of the resected tumor showed it to be composed almost exclusively of functionally inactive delta type islet cells. Both the unusual microscopic composition and biologic behavior of this neoplasm appear worth recording.

CASE REPORT

A white female 40 years of age was first admitted to the pre-clinic on August 7, 1933 complaining of a periodic gnawing sensation in the epigastrium which appeared 1 to 2 hours after eating and radiated posteriorly to her back. These episodes had been present intermittently over a period of 4 years with symptomless intervals lasting 1 to 2 months. The pain was relieved by taking food and aggravated by fatigue. Her appetite was usually good apples were recorded as the only food for which she had an idiosyncrasy. There was no history of hematemesis, icterus, bloody or tarry stools. Investigation of her past history showed that 5 years previously she had had a uterine suspension and appendectomy per-

formed. Her convalescence was complicated by postoperative pneumonia. There had been no other known illnesses. Her husband had died some time previously and was reported to have had acquired central nervous system syphilis. A son by him exhibited interstitial keratitis. The patient had not received antiluetic therapy and two blood Wassermann reactions taken at this time were recorded as negative.

The patient was an obese, white female, weighing 203 1/2 pounds who presented tenderness to palpation in the epigastrium and over both right lower and upper abdominal quadrants. No masses were palpable. Some tenderness was present at the right costovertebral angle at the level of the 11th and 12th dorsal vertebrae. A roentgenologic study of the gastroenteric tract August 8, 1933 showed the stomach to be of the high transverse type exhibiting hypertonicity and hypermotility. No mucosal defects were demonstrable in the stomach or duodenum. Gastric analysis (Ewald test meal) showed a total hydrochloric acid content of 74 degrees and a limited acidity of 90 degrees. She was placed on a limited diet with alkali administration which relieved her pain and produced general subjective improvement. She was observed at intervals in the out patient department until 1935 when it became impossible to continue her visits as she was unable to take leave from her job to attend the clinic. She stated that she felt well except when she neglected to take the alkaline powders. She was not seen again until April 11, 1938 when she visited the gastric clinic after an absence of about 3 years. She stated that she had been well and free of symptoms until September 1937 when her previous complaints returned and became progressively more severe. She was forced to remain in bed during the month of February. Once during this period she suffered an attack of vomiting which culminated in a severe gastric hemorrhage and she was brought to a hospital and placed under observation for 1 week. Improvement under treatment was rapid though she continued to complain of a burning sensation in the epigastrium. She was advised to continue on a Sippy diet. Her weight was now 165 pounds. There was moderate tenderness to palpation in the right upper quadrant and pain was elicited over the descending colon. A firm mass having a sharp irregular edge was palpated below the costal margin in the left upper part of the abdomen. This was tender to pressure and was thought to be the spleen. Roentgenologic study performed on April 18, 1938 and repeated on May 3, 1938 showed the duodenal cap to be definitely deformed and irritable with extremely marked

SURGERY GYNECOLOGY AND OBSTETRICS

localized tenderness present. A diagnosis of acute duodenal ulcer was made. A blood Kahn test performed May 10 1939 was negative. The red blood cell count was 3,600,000 and the white blood cell count 5,000. Considering that the palpable mass in the left upper abdominal quadrant might represent a misplaced kidney, the patient was admitted to the hospital on the genitourinary service. Flat plates of the abdomen and bilateral retrograde pyelograms failed to reveal any renal abnormalities. She was discharged to the gastric clinic for further observation. On June 2 1938 a barium enema showed the palpable mass in the left upper abdominal quadrant to be medial to the descending colon and at the level of the lower pole of the left kidney. The colon was not displaced in this region. A gastroenteric series on July 19 showed no essential changes in the duodenum from the previous examination and the patient seemed improved on the prescribed therapy. On May 15 1939, she again returned complaining of having vomited intermittently during the preceding 5 weeks and of being unable to retain any food during the past week. She was admitted to the hospital feeling very weak and continuing to suffer from abdominal pain and repeated vomiting. The red cell count was 4,170,000 and the white blood cell count 8,500. The mass noted in the left upper abdominal quadrant remained unchanged to palpation and no new light was shed on its nature. She again responded well to medical treatment for her duodenal ulcer and was discharged as improved 1 month after admission and advised to continue on a Sippy diet. A return of her ulcer symptoms sufficiently severe to require hospitalization occurred again on October 31 1940. Physical examination was essentially unchanged from the last hospital examination. The roentgenologist now demonstrated the presence of a diverticulum of the proximal part of the second portion of the duodenum with irritation of the entire first and second portions and suggested that the mass might be in the pancreas. A spinal fluid Wassermann and gold curve were recorded as negative on December 12 1940. The patient was discharged on January 11 1941, with a clinical diagnosis of diverticulitis of the duodenum with probable ulcer formation. She was placed on Sippy powder and atropine. She was instructed to return to the gastric clinic. On January 29, 1941, she was readmitted with a familiar story of epigastric pain and vomiting. A severe attack of hematemesis had occurred 2 days prior to admission. Physical examination showed that the abdominal mass in the left upper quadrant first detected 5 years previously was present but no diffuse epigastric tenderness was present. A blood pressure reading was 132/85. The red blood cell count was 3,760,000 and a white blood cell count 13,700. Examination of a stool specimen for occult blood gave a slightly positive reaction to the guaiac test. Diagnosis of penetrating duodenal ulcer was made. Gastric resection was believed to offer the best hope for lasting relief of her symptoms. The upper left quadrant abdominal mass was thought to represent matted loops of adherent intestines and omentum, the result of leakage from the ulcer crater. The possibility of a retroperitoneal neoplasm of undetermined type was also considered.

On February 26 1941 an exploratory laparotomy was performed. The scar of a duodenal ulcer crater was seen and felt, but there was no crater present and no signs of activity. On exploring the left upper abdominal quadrant a circumscribed hard nodular mass was made out in the region of the body and tail of the pancreas. Closer inspection showed it to have apparently replaced most of this organ and to be adherent to the jejunum, stomach, and spleen. It was firm, well encapsulated larger than a fist, and fairly freely movable. No metastases could be made out. The mass was exposed through the gastrocolic ligament carefully dissected free and removed *in toto*. A large vein penetrating the mass was thought to be occluded by tumor tissue. It was stripped of its contents and ligated. The patient thereafter made an uneventful recovery. Gross examination of the excised tumor mass showed that the specimen consisted of a well encapsulated nodular grayish-white mass 12 by 8 by 6 centimeter in diameter. Firmly adherent to one portion of its surface and blending intimately with the substance of the pancreas was a flattened well lobulated portion of the tumor was about 2 by 2 centimeter in diameter. Elsewhere small tabs of adipose tissue were adherent to the tumor surface. The cut surface of the tumor was uniformly dark reddish-gray, one as though necrotic. Several small portions were removed from the surface of the tumor for microscopic examination. The remaining large mass was sectioned across its greatest axis into two equal halves. One of these was prepared for paraffin embedding on bloc the other used for further sectioning and study with different stains. The generous size of the tumor even if allowance is made for previous trimming and shrinkage following fixation, can be appreciated (Fig. 1).

Microscopic examination of sections taken from some hypertrophied portion of the pancreatic tail showed the still undamaged acinar tissue. The cells composing the islets possessed a rather abundant clear cytoplasm enveloping their uniform round central nuclei. This cell type bore a striking resemblance to small compact round areas of tumor infiltrating the tissue within the acinar areas of the gland (Fig. 2). The cell nuclei of the tumor cells however were larger the chromatin sparse and irregularly disposed in small threads. No nucleoli were present. With ordinary stains the appearance of the nuclei was unlike that of alpha or beta type cells. The tumor cells ranged from about 15 to 20 micra in diameter with the nuclei composing slightly more than one

half of the cell diameter. Special stains for cytoplasmic detail, by means of both the Mallory Azan and the Gomori techniques failed to reveal the presence of alpha or beta cell granules. Sections taken from numerous widely separated portions of the tumor showed a strikingly uniform cell type and arrangement resembling the delta cell of pancreatic islet tissue. In most instances the tumor was composed of broad sheets divided by elongated connective tissue trabeculae of varying thickness (Fig. 3). Some zones were completely walled off into circular nests of round and oval cells. In a rare zone the cells became more columnar resembling duct epithelium. The cytoplasm of the cells in the larger zones stained light pink with eosin with an occasional one showing a clear zone about the nucleus. All portions of the tumor possessed a rich vascular supply. About some capillaries the cells assumed a rosette pattern. In a few areas small clumps of cells were found lodged within the lumina of the vascular channels. No portion of the tumor showed any striking variation in cell size or shape. Mitotic figures were present but not numerous. The thin capsule surrounding the tumor was invaded by nests of uniform tumor cells at many points and these cells also penetrated adherent tags of adipose tissue. One attached small pericapsular lymph node embedded with the adjacent fat was almost entirely replaced by tumor.

On account of the finding at operation of tumor in the lumen of a large vein she was given postoperative deep x ray therapy and received 10,400 roentgen units between March 17 and April 25 1941. For several months she complained of some pain in the region of the incision but this gradually disappeared and at her last examination at the clinic on February 20 1942 she was remarkably free of any symptoms. Roentgenologic examination December 17 1941 still showed deformity of the duodenal cap and the presence of a diverticulum of the second portion of the duodenum.

Fig. 3. Cross section of original tumor after fixation and staining.

The patient was seen again May 15 1943, by request. She had remained free from any digestive disturbances. Her appetite was good and she had regained her usual weight weighing 210 pounds. She said that recently there had been some discomfort in the abdomen to the left of and just above the umbilicus. On examination the incision was well healed but an indefinite mass could be felt in about the position occupied by the original tumor. This mass was difficult to outline because of her obesity but apparently did not descend with res-

Fig. 2. Portion of tail of pancreas infiltrated by tumor cells bearing a resemblance to islet tissue.

Fig. 3. Broad sheets of uniform appearing cell types composing the bulk of the tumor.

SURGERY GYNECOLOGY AND OBSTETRICS

piration. The liver was not enlarged and the spleen could not be felt. A ray films of the gastroenteric tract showed the stomach to be of the transverse type. There was slight deformity of the transverse bulb. The second and third portions of the duodenal stomach but did not displace it. The colon was negative roentgenologically and its relation to the mass was not determined. The lungs and mediastinal structures appeared normal. Clinically it seemed likely that the tumor had recurred. In the absence of any striking symptoms she was unwilling to consider any further studies or exploratory operation at this time.

In July 1943 the patient consented to enter the hospital for a glucose tolerance test which was essentially normal.

Fasting	Milligrams per cent
1 hour	95
2 hours	26
3 hours	6
4 hours	93
	8

About 1 year later July 13, 1944 she entered the hospital complaining of headache of several months' duration and vomiting of 4 weeks. She also had attacks of dizziness. She said she had lost about 20 pounds in weight though he still weighed 192 pounds. The liver was found to be moderately enlarged with a nodular edge and a mass on the left side about the size of a fist was found. A glucose tolerance test again showed an essentially normal pancreas as follows:

Fasting	Milligrams per cent
1 hour	97
2 hours	57
3 hours	63
4 hours	3
	95

A blood sugar determination made from blood taken during one of her dizzy spells was 83 milligrams per cent.

On August 1, 1944 a laparotomy was performed and disclosed a recurrent tumor involving the pancreas numerous nodules in the liver and several in the mesentery and omentum. One nodule about 3 to 3 centimeters in diameter in the omentum was removed. Microscopic examination showed an appearance exactly like that of the original tumor.

The patient was discharged from the hospital September 2, 1944 apparently improved. She had minor attacks of abdominal pain and occasional vomiting for which she was given fairly large doses of tincture of opium. On November 6, 1944 she was suddenly seized by intense epigastric pain and vomited coffee ground material. She was admitted to the hospital and although it seemed of virus that she had had a severe intra-abdominal accident, she was treated by nonoperative measures in view of the known extensive malignant disease. Continuous

gastric suction and large doses of opiates gave her considerable symptomatic relief but the temperature and pulse rose and she died November 10, 1944.

Autopsy was performed 3 hours post mortem, the following being an abstract of the pathologic report.

Anatomical diagnoses were (1) mesenteric lymph nodes with infarction of jejunum and hemorrhagic metastasis to liver, urinary bladder, uterus and mesentery. (2) duodenal ulcer (chronic).

On opening into the peritoneal cavity 15 cubic centimeters of blood tinged fluid was found. It was immediately noted that a section of jejunum 30 centimeters in length had a dark purple-red surface. This extent of bowel was very slightly dilated but no constriction, volvulus or telescoping was found. The mesentery of this segment of intestine was very dark red and anteromortem blood clots were demonstrated in the branches of the mesenteric arteries and veins. The portal vein was occluded by an old blood clot and apparent tumor mass. The head of the pancreas was replaced by a tumor mass 12 centimeters in diameter which projected behind the duodenum and into the lesser curvature of the stomach. The tissue was granular and varied in consistency from mushy to moderately firm. The tail of the pancreas was replaced by another large tumor mass measuring 6 centimeters in diameter. No normal pancreatic tissue was recognizable. The spleen vein was surrounded and occluded by tumor growth. The regional lymph nodes appeared normal (irregularly) roughened external surface due to a projection of nodules varying in size from 1 to 4 centimeters in diameter. These nodules were soft, mushy and white on the cut surfaces. They were manifestly neoplastic and occupied a considerable proportion of liver volume. The recognizable liver was dark brown, soft and slightly friable. Part of the portal system was occluded by tumor growth.

Microscopic examination revealed giant cell carcinoma of the pancreas with massive infiltration of the liver widespread necrotizing nodal necrosis of the liver severe hepatitis organizing phlebotomies marked glycogenic infiltration of liver mesenteric venous thrombosis with jejunal infarction and early gangrene acute mesenteric arteritis splenic infarction chronic interstitial fibrosis of pancreas organizing thrombus of pulmonary arterioles mild focal atelectasis and pulmonary emphysema.

The tumor tissue obtained at post mortem took exactly like the original tumor and the metastatic nodule removed in August 1944.

SUMMARY

A large tumor of the pancreas was removed from a 48 year old woman who was known to have had a palpable mass in the abdomen for 2 or 3 years but whose symptoms were

those of duodenal ulcer. Study of the tumor showed it to be an islet cell tumor of the pancreas. Gross findings at operation and microscopic study indicated that it was malignant. At no time were there any symptoms of hypoglycemia and several glucose tolerance tests were normal. Local recurrence and widespread metastases occurred and the pa-

tient died 3 years and 10 months after removal of the tumor the immediate cause of death being mesenteric thrombosis.

THE SURGICAL REPAIR OF THE DEEP BRANCH OF THE RADIAL NERVE

FRANK F. ALLBRITTEN, Jr. M.D., First Lieutenant, M.C. A.U.S., Philadelphia, Pennsylvania

THE injuries to the extremities in war result in large numbers of peripheral nerve injuries. In a 12 months period 329 explorations of peripheral nerves have been done at this hospital. Of these 232 were operations for nerve injuries in the upper extremities, 51 were explorations of the radial nerve. In 15 instances the radial nerve has been explored distal to its point of division into the deep (motor) and superficial (sensory) branches.

The injuries to the deep branch of the radial nerve have been due to penetrating wounds of the forearm, extensive soft tissue wounds and fractured bones of the forearm have been the usual associated injuries. The deep (motor) branch of the radial nerve is well protected from pressure, contusion and superficial injuries. Its injury is rare in civilian life and the characteristic deformity and function loss are most often seen in the regenerating common radial nerve before the regenerating axones have reached the most distal muscles or those supplied by its deep branch.

It has been regarded that the repair of the radial nerve distal to the point of division into the superficial and deep branches is generally not satisfactory. This was thought to be due to the small caliber of the radial nerve distal

to its point of division and because of the difficulty in obtaining sufficient length to close any appreciable defect existing in the continuity of the nerve. Mayfield found these unfavorable factors in the technique of nerve repair could be overcome and usually a satisfactory repair could be accomplished. There are two especially favorable conditions for regeneration in this particular nerve: first, it carries only motor fibers and, second, only a short distance must be bridged before the regenerating axones reach their motor end plates.

Interruption of continuity of the radial nerve distal to the origin of the deep and superficial branches is also distal to the site of origin of at least one motor branch to the extensor carpi radialis muscle group. Consequently extension of the hand at the wrist is not lost, though it is impaired. In the position of extension the hand has a characteristic radial deviation due to the loss of function of the extensor carpi ulnaris muscle. Associated with this functional deformity at the wrist is the loss of extension of the metacarpophalangeal joints of the fingers and thumb, the loss of extension of the distal phalanx of the thumb and abduction of the thumb (Fig. 1).

Such a lesion produces a characteristic deformity as well as serious functional loss.

Fig. 1

Fig. 1. Characteristic deformity associated with deep radial nerve paralysis. Note extension of first thumb radial deviation, loss of extension of all metacarpophalangeal joints and loss of abduction of thumb.

Fig. 2

Fig. 2. Side view of characteristic deformity. Loss of abduction and extension of thumb obstructs entry of objects into grasp of fingers. Loss of extension of fingers reduces the reach of the grasp and impairs fine movements of fingers.

Fig. 3. For illustration the extensor carpi radialis muscles have been divided transversely and reflected. The deep branch of the radial nerve spirals posteriorly around the neck of the radius and passes between the superficial and deep planes of the supinator brevis muscle. The extensor carpi radialis brevis and the extensor digitorum communis muscles have been separated to expose the branching of the deep radial nerve as it emerges from the supinator brevis muscle.

Fig. 3.

Grasping objects is greatly impaired as the dorsum of the thumb impinges on the object. The thumb must first be abducted with the opposite hand in order to encircle the object and oppose the fingers. The fingers cannot be extended to open the hand for grasping; the dorsum of the fingers is slid over a fixed object until the finger tips pass over it and it then comes under the flexion function of the fingers. The loss of fixation of the metacarpophalangeal joints by the extensor tendons results in loss of fine movements of the fingers. Abduction and adduction of the fingers are impossible unless the metacarpophalangeal joints can be extended (Fig. 2). The functional loss resulting from a lesion of this terminal branch is almost as disabling as the loss of the common radial function of the mid arm. Interruption of the continuity of the motor branch of the radial nerve distal to its site of division may result in loss of any one of the functions mentioned depending upon the nerve branch injured (Fig. 3).

Fig. 4 Dissection of radial nerve showing injury to radial nerve proximal to site of division and site of foreign body in the deep branch. The entire area was resected and a satisfactory end-to-end suture accomplished. 1 Common radial nerve. 2 scar between common radial nerve and superficial and deep radial nerves. 3, deep branch of radial nerve. 4 superficial branch of radial nerve.

Fig. 5 Findings at operation of patient shown in Figure 3. There is scarring of the deep branch of the radial at its site of division. The extensor carpi radialis and the extensor communis digitorum muscle group have been separated. The vein retractor is holding back the cut superficial portion of the supinator. The branches labeled show the muscles supplied. A branch arising below the supinator muscle to the extensor carpi radialis longus muscle is commonly demonstrated by electrical stimulation though not generally described in the anatomical texts. 1 Deep branch of radial nerve. 2 nerve to extensor carpi radialis muscle group. 3, nerve to extensor communis digitorum muscle. 4, nerve to extensor carpi radialis brevis muscle. 5, nerve to extensor carpi ulnaris and extensor digiti minimi muscles. 6, nerve to abductor pollicis longus and brevis muscles.

The anatomy of the nerve can be described by the surgical approach. An incision is made on the anterolateral aspect of the lower third of the arm lateral to the elbow joint. It is continued on the dorsum of the forearm to the junction of the middle and lower thirds of the forearm in the palpable groove between the extensor carpi radialis muscle group and the extensor digitorum communis muscle. Such an incision passes posterior to the lateral cu-

taneous and anterior to the posterior cutaneous nerve of the forearm and does not cross the flexion crease of the elbow. It allows the anterior border of brachioradialis muscle in arm and forearm and line of cleavage between extensor communis digitorum and extensor carpi radialis muscles to be easily explored.

The cleavage line between brachioradialis and brachialis muscles is then developed and as the brachioradialis muscle is retracted lat-

Fig. 6. End-result in Case 2. Note tendons of extensors and abductor of thumb. There is residual weakness of the extensor of the middle finger.

Fig. 7. Result in Case 3. Note loss of most proximal portion of substance of extensor muscles from initial débridement of wound. The residual muscles provide satisfactory extension and abduction of the digits following nerve regeneration.

erally the common radial nerve is exposed. Branches to the brachioradialis and extensor carpi radialis longus muscles emerge from the lateral side of the nerve. The medial side is safe for dissection.

The radial nerve usually divides into the superficial and deep branches at about the level of the elbow joint (Fig. 4). The more medial or superficial branch of the nerve can be traced downward into the forearm beneath the brachioradialis muscle. It becomes subcutaneous in the distal third of the forearm. This is a purely sensory nerve and its injury is of minor importance when compared to the injury of its motor division.

The second terminal branch of the radial nerve is ordinarily known as the posterior interosseous branch, the deep branch, or the motor branch. This nerve passes anterior to the capsule of the elbow joint, then continues laterally and posteriorly to curve about the neck of the radius beneath the superficial portion of the supinator muscle. A motor nerve branch to the supinator muscle is usually given off the lateral side of the deep radial nerve a short distance above its passage into the supinator muscle.

To expose the nerve distal to the supinator muscle the dissection is made on the dorsum of the forearm. There is a palpable groove

between the extensor carpi radialis and the extensor digitorum communis muscles in the middle third of the forearm and dissection will develop this line proximalward along the intermuscular septum from which some of the muscle fibers of both groups of muscles originate. When the extensor carpi radialis muscles are retracted laterally and the extensor communis digitorum muscle is retracted medially the deep branch of the radial nerve will be exposed at its point of emergence from the supinator muscle. Medial branches to the extensor communis digitorum and additional lateral branches to the extensor carpi radialis muscles are given off only a short distance from its site of emergence from the

Fig. 8. Result in Case 4. Near complete abduction of thumb and extension of the digits has been regained.

Fig. 9. Extension of wrist and digits obtained by tendon transplantation. Deep radial nerve was irreparable.

TABLE I

Case No.	Date	Location of lesion in relation to supinator muscle	Defect in cm	Operative procedure	Result
	6-30-44	Distal	4	Repair	Return of function (Fig. 6)
	7-10-44	Distal	5	Unsatisfactory repair	Lost to follow-up
3	9-1-44	Distal		Repair	Return of function (Fig. 7)
4	9-30-44	Proximal	4.5	Repair	Return of function (Fig. 8)
5	0-2-45	Distal		Neurolysis	Lost to follow-up
6	2-15-45	Proximal and within		Irreparable	Tendon transplant
7	2-23-45	Within (this and distal)	8	Irreparable	Tendon transplant

supinator muscle. The nerve then becomes much smaller in caliber and may give off additional medial and lateral branches but the main trunk continues distalward to reach the extensor pollicis longus and brevis and the abductor pollicis longus muscles. These are terminal branches of the nerve (Fig. 5).

In the surgical exposure of the deep branch it will probably be necessary to incise the superficial portion of the supinator muscle in order to obtain complete visualization and gain length to obtain an approximation if a segment of the nerve has been destroyed. Transplanting the nerve superficial to the supinator and elevation of the common radial to a more superficial position beneath the brachioradialis and flexion of the elbow with the nerve transplanted more superficially permits large gaps to be sutured without tension. An accurate approximation of only the epineurial sheath with fine suture material with out tension is the essential requisite for nerve suture. The minimum of foreign body and trauma at the line of suture insures minimal inflammatory reaction and fibrosis. If the nerve is injured at the site of its branching the distal filaments should be approximated by fine sutures through the sheath in order to form a single distal trunk. A more satisfactory end-to-end suture can be obtained in

this way than in trying to suture each branch to the single proximal trunk. Following suture of the nerve the elbow is immobilized in a position of flexion for a period of 4 weeks and then gradual extension is permitted to take place.

To close a defect by stretching the nerve either at the time of operation or postoperatively results only in fibrosis of the stretched section and prevention of regeneration. It will be impossible to repair some defects even after an extensive mobilization and transplantation of the nerve to a more superficial position. In these patients tendon transplant will have to be resorted to. The defects in the deep radial nerve in this group of patients are listed in Table I. In the 15 patients in which the deep radial nerve was explored it has been possible to obtain a satisfactory end-to-end suture in 8. In 3 of these sufficient time has elapsed to expect regeneration and all 3 have shown excellent return of function (Figs. 6, 7 and 8). Four have been regarded as technically irreparable due to extensive loss of nerve tissue. Of these 3 have been referred to the orthopedic section for tendon transplants (Fig. 9). A neurolysis has been done in 3 patients. In these continuity of the nerve was intact. Two of this group have had return of nerve function since the neurolysis was done.

SUMMARY

The results to date in 15 cases of exploration of the deep or motor branch of the radial nerve are given.

The deep or motor branch of the radial nerve should regenerate well because of its purely motor character and the short distance regenerating axones must span before reaching their motor end plates.

The characteristic deformity and function loss is described and the surgical anatomy discussed. By sufficient mobilization and transplantation of the nerve moderate defects in the continuity of the nerve may be closed and satisfactory repair may be accomplished.

The early results have been sufficiently good to warrant exploration of injuries to the terminal motor portion of the radial nerve with an attempt to restore its continuity. If destruction of the nerve is of such extent that repair is impossible tendon transplant to obtain extension of the digits and abduction of the thumb should be done.

Additional data have been obtained since this paper was submitted for publication. Twenty-four explorations of the deep branch of the radial nerve have been done in 14 instances, as listed in Table I. The nerve was irreparable. Sixteen of the nerve was required in 3 patients. Of these, 9 have shown return of function, 2 are showing beginning return of function, and 2 have shown no evidence of regeneration. Lysis of the nerve was done in 7 patients. All have shown return of function.

THE TREATMENT OF BURNS

Report of 155 Cases

WALTER C. BORNEMEIER, M.D., F.A.C.S., Major M.C., A.U.S. Chicago, Illinois, and
LANGDON PARSONS, M.D., F.A.C.S., Lieutenant Colonel M.C., A.U.S. Boston Massachusetts

THIS series of burns includes 155 patients admitted and treated during 1 year. There were 97 admitted from forward hospitals where the primary dressing was done and 58 admitted directly from the scene of accident with first aid but without initial definitive care. Twenty six cases or 17 per cent of the entire series, were third degree burns the percentage being about the same in the two groups.

This discussion will concern itself almost entirely with the treatment of third degree burns with a description of the methods used and with emphasis on strict adherence to established surgical principles. Not much attention has been paid to the type of emollient used for primary dressings because throughout the series it has been observed that other factors seemed more important. In the group of patients admitted from forward hospitals, a wide variety of materials was used in the group admitted here directly from the scene of accident, all were treated identically and the results were similar in the two groups. It was felt, therefore, that factors other than the emollient were the ones to consider as important. Gradually throughout the series, an attempt was made to improve technique and shorten the time required to get complete skin coverage. By the end of the series, we were accomplishing our aim of obtaining complete skin coverage of third degree burns within 4 weeks of the date of injury.

CLASSIFICATION

Before discussing treatment it is important to establish the method by which a first, second or third degree burn was diagnosed. When erythema only was noted the diagnosis was first degree. When erythema plus blisters appeared the tissue under the blister was inspected as well as could be done without dis-

turbing the blister. When the base of the blister revealed the dermis to be pink and covered with a network of fine blood vessels appearing as multiple red dots a diagnosis of second degree burn was made. However, when the dermis under the blister was sallow in appearance or there were only a few visible vessels a diagnosis of third degree burn was made. Naturally if the destruction went beyond the blister stage to charring the diagnosis was obviously third degree. In all patients admitted from forward hospitals, the diagnosis made at the forward hospital was accepted and recorded. In only 1 instance was it necessary to change the diagnosis this injury being a phosphorus burn which was originally called second degree but which eventually required grafting of skin. Certainly infection in the management of these patients did not make third degree burn wounds out of those that should have healed without operative repair.

INITIAL TREATMENT

All cases of the two groups had the following treatment (1) prompt attention (2) plasma 50 cubic centimeters for each 1 per cent of body surface burned given during the first 24 hours (3) morphine for comfort (4) thick pressure dressing with fine mesh gauze next to the burn over a nonirritating emollient (5) immobilization by the use of pressure dressings with stockinette or elastic pressure (6) warmth and rest (7) no change of primary dressing for 7 to 10 days.

All patients from forward installations arrived here in about 4 to 6 days in excellent condition taking a full diet. In a few the dressings needed to be reinforced because of shifting in transportation but most of them required no immediate care.

All of the 58 patients admitted directly to the hospital from the scene of the accident had identical care. They were taken from re-

From a hospital in the Communications Zone.

ceiving to the operating room where all the personnel were required to wear masks and where sterile technique was followed. None of them was anesthetized none was debrided. Blisters were not disturbed. When mud or dirt from the street had soiled the burned surface it was washed gently with a warm mild soap solution. When no obvious surface contamination was present, no cleansing was done. Some were brought in with a thin dressing over the wound a few had had a topical application of an ointment. These dressings were removed but no effort was made to remove any medication. Morphine in the meantime was given to those who had none before admission and plasma was started at once by the operating room personnel. As rapidly as possible sulfadiazine cream in fine mesh gauze strips which is kept available for that purpose, was laid smoothly over the burned surface. Gauze pads, followed by full thickness cellulose absorbent pads were applied then sheet wadding and plaster of paris for extremities, in order to get maximum immobilization. A section of stockinette was used over the heavy pads for the face and head with holes cut for eyes, nose and mouth. Over the trunk the padding was supported by ace bandage.

Even in the extensive burns, the dressing was completed by the time 1 unit of plasma had been given, so the patient, having been kept warm in the meantime, was taken to the ward and put to bed. A note indicating how much plasma he was to receive accompanied the patient to his ward. This amount was calculated rapidly on the basis of 1 unit for each 5 per cent of body surface and usually the entire amount was given promptly without interruption in order to prevent hemoconcentration and shock. Warm drinks, rest and quiet were the rule for these patients and usually in a few hours they were ready to eat. Even though many patients had severe burns none developed shock, probably because of the prompt administration of a calculated amount of plasma. Within the first 24 hours copper sulfate determinations were done to evaluate the hemoconcentration. Plasma or whole blood was given as indicated. On the seriously or extensively burned patient, this checkup was repeated frequently during his

entire stay in the hospital and blood or plasma supplied whenever indicated. After the initial amount had been given, very few patients required additional plasma. Whole blood, however was used in the later treatment of some patients and will be discussed later.

Of the 129 first and second degree burns, all returned to duty. They had an average of 8 per cent body surface burned and were in the hospital an average of 28 days. No complications developed in this group and none required transfusions. All were treated by initial pressure dressings. Some received chemotherapy others did not, and since the results were good gradually less attention was given to chemotherapy in the first and second degree burns. This subject will be discussed in more detail under a separate heading.

LATER TREATMENT

In the first and second degree burns, dressings were changed at approximately 8 to 10 days. These patients were without exception taken to the operating room where sterile technique was the rule. All were premedicated with morphine and atropine, and sodium pentothal anesthesia was used whenever the change of dressing was painful. In approximately half of these cases no subsequent dressing was required. When required areas were cleansed with warm saline sponge fine mesh gauze strips, dry or impregnated with sulfadiazine cream, were laid smoothly over the burned surface and were covered again by padding and pressure immobilization exactly as at the initial dressing. Dressings were changed in the operating room at about weekly intervals until recovery.

In a few cases there was some evidence of exudate and infection but no cultures were made. This infection cleared rapidly and in no instance did it become a cause for a change in the management of the first and second degree burns. All of these soldiers returned to duty in this theater of operations.

The third degree burns cannot be dismissed as simply and it is with these patients that we were most concerned. Their management required the utmost patience and persistence and after the initial few days had elapsed their treatment was aimed at prevention of infec-

tion coverage by skin grafting and supportive measures. It was our observation that the longer skin coverage is delayed, the greater is the problem of infection and supportive therapy. Also the greater the infection the more difficult the skin coverage. It thus became a race between the surgeon with his skin grafts and the wound with its bacteria.

In this series there were 26 patients with third degree burns, with an average of 20 per cent of body surface involved, all of whom required skin grafts. Two distinct types of pathology were noted in these wounds. Those who had damage but not destruction of the full thickness of skin usually had a gradual slough of dermis down to the subcutaneous tissue during the first 2 weeks. Under this slough then appeared the granulating surface. Usually the sloughing was not complete at the first dressing so the patient was redressed and returned to the operating room in about 4 days. Usually by this time 2 weeks after the burn skin replacement was started.

The other type of third degree burn encountered was that in which the entire thickness of skin had been destroyed. By 14 to 21 days the entire area was well demarcated. It has been our experience that it is best not to wait for this eschar to loosen and it is a decided mistake to leave it intact until fluid collects under it. As soon as the area of demarcation became evident, the entire eschar was removed by sharp dissection. This procedure was usually carried out about 2 weeks after the burn. Very little bleeding was encountered and secondary hemorrhage was controlled by pressure dressings. In a few days the area was covered by granulation tissue and grafting was started.

On several of our recent patients we have placed very thin grafts directly on the subcutaneous fat at the time of removal of the destroyed skin without waiting for granulations to form and we have been gratified to see that about 90 per cent of these grafts were successful. In the future we expect to start grafting promptly after removal of the eschar because from the standpoint of infection the area is as clean as it ever will be.

It has been our experience that from the time the damaged or destroyed skin is re-

moved skin replacement must be pushed vigorously until the entire area is covered. Naturally in extensive burns it is impossible in most instances to do a complete coverage at one operation. The length of the period of anesthesia and the availability of donor sites limit the amount of work that can be done. No other factor however should be permitted to delay the procedure. In some of our early cases we delayed because it was felt that the area was in no condition to receive skin. Always this was later regretted. It is difficult to improve an area and the probability of its becoming worse is very real. In a number of instances in which we have grafted areas that were thought to be poor recipient sites we have lost the grafts but almost always the area improved sufficiently by the skin dressing so that the next attempt was successful. Skin dressing has been our most successful agent in combating infection with its complications. One of our recent patients with 35 per cent body surface involved had the eschar dissected and removed on the 14th and 18th day after being burned. The grafts were applied the 18th, 22d and 27th day and the area was completely covered at that time. He may require a few minor plastic procedures in the future but certainly he has been saved months of disability by prompt and vigorous application of skin.

SKIN GRAFTING

The procedure of skin grafting in the treatment of burns is not the problem of a plastic surgeon. The primary purpose of transplanting skin is to facilitate rapid wound healing in order to preserve the deeper structures involved and maintain the general condition of the patient. Whatever procedures might be necessary later to improve the skin function of the grafted area was not given too much consideration at the time of the original grafting. Whenever possible thicker and larger grafts were placed in the axilla popliteal space, and other areas where danger of cicatricial contracture is present, but always the type of graft that was most certain to grow was used. The healing of the wound and preservation of the muscles vessels tendons and joints were the primary considerations.

Then if the individual could be cured of his burn remain in good general condition with no loss of function of deeper structures, and be completely covered by good skin instead of tender adherent contracting scars we felt that the treatment of the burn had been adequate. Whatever later skin substitution is necessary becomes a problem for the plastic surgeon but originally skin coverage was done to save the patient, prevent sepsis and preserve function. Speed of coverage was the watchword and small thin grafts lent themselves better to this type of surgery than larger and thicker sections.

TECHNIQUE

In an effort to get skin coverage in the shortest possible time we have tried several methods of grafting. Because of the pressure of work in this theater of operations and since burns seemed to occur when casualties were heaviest, their care coincided with the care of many other injuries. Also with occasional change of personnel simplification of technique was necessary.

At first we followed the accepted technique of cutting grafts and placing them in saline as they were removed. After all the grafts were cut, they were spread on a moist rubber dam and transferred to the recipient site. This procedure involved unfolding and smoothing out curled edges, as the graft slipped to and fro on the recipient site and possibly suturing the graft in place. This method was so time consuming and irksome that it was finally discarded.

Next we tried a method which as far as we have been able to determine has not been advocated probably because of the possibility of infecting the donor site. This method is the immediate direct transfer of skin from the donor to the recipient site without passing through saline. We were surprised and pleased with the result. First, it reduces the time required to cover a given area to about one-fourth of the time needed when the section is passed through saline solution and permitted to contract and curl up. Second the adhesive quality of the freshly cut surface causes it to nestle and cling to its new bed so tenaciously that in a matter of minutes it is

almost impossible to disturb it. Sutures are never necessary.

By the direct transfer particularly of small easily handled sections the cutting instrument carries the graft to its new site, and a forceps or any available instrument fixes one end of the section. The knife, as it is pulled away smooths the graft over its new home. Even the under sides of suspended extremities can be grafted easily. Graft after graft is laid end to end and side by side, going to and from the donor site so that an entire extremity can be covered in the time ordinarily required to cover the anterior aspect of a leg. The procedure is done easily rapidly without annoyance the grafts adhere well, grow readily and skin grafting becomes a pleasure. No infection of donor site has occurred.

In recent years, much has been written on the application of adhesive substances to the grafts or recipient site. We have had no experience with the acacia preparation or plasma thrombin or with any other adhesive substance, but believe its use is sound. However, by the immediate direct transfer without washing in saline, we have preserved nature's own adhesive substance to fix the graft to its new location without the use of added adherent.

After the grafts were placed fine moist gauze moist but not wet, was laid evenly over the area. Gauze pads and abdominal pads for gentle pressure were applied. Plaster of Paris casts were put on extremities ace bandage was used over the trunk, with figure-of-8 for the buttocks and 8 inch stockinette hood for the head and face. Donor sites were sprinkled with sulfanilamide crystals and covered in the same manner as was the grafted area. Four to 6 days later the patient was brought back to the operating room for subsequent grafting of additional areas or a patch here and there where a small area failed to obtain coverage.

Most of our grafts were cut very thin, the average thickness of grafts being less than 0.010 inch. In our experience generally speaking the thinner the graft, the better it will grow. Also the recovery of the donor site was much more rapid when thin sections were used. This factor was important in the 11 cases in the series of patients who had over

25 per cent of body surface involved. In these cases it was sometimes necessary to use some of the donor sites more than once. It has been our observation however that skin cut from a previously used site does not grow as well therefore we used a fresh site whenever possible. Most of the donor sites were healed sufficiently to go without dressing in 8 days.

INSTRUMENTS

In an active theater of operations where the patient load at times may become tremendous the problem of keeping instruments available and in working condition is a very real one. With a large number of burns requiring grafts and several surgeons at work every instrument that was available adaptable to skin grafting and sharp was pressed into service. When the donor sites were adequate the Padgett dermatome available and blades sharp, the dermatome was used. However since sections cut with the dermatome did not lend themselves easily to direct transfer the Blair knife or a Gillette type razor blade was used more often and the dermatome used only for the coverage of special areas such as axilla or popliteal space. The razor blade grasped by a curved Kelly forceps, was the ideal instrument when small sections were desired or only a spot here and there needed to be covered. It can be used well by anyone. Those of our group who had never done skin grafting became experts in one easy lesson. By grasping the blade with a curved forceps, held in the right hand while the left hand steadies the field a strip of skin an inch wide and as long as the donor site will permit can be cut rapidly and easily without assistance. This method lends itself well to the direct transfer of grafts. It has the added advantage of always being available and sharp. A supply of razor blades was kept in sterilizing solution so that the decision of whether or not to graft was never influenced by the availability of sharp instruments.

With rapidly healing donor sites availability of sharp instruments, and simplicity of method our group rapidly assumed the attitude that skin is expendable and grafts were placed whenever and wherever possible. In fact some grafts were placed on recipient sites

that looked impossible frequently with very gratifying results. For example, an area from which a charred eschar was dissected 10 days after being burned had skin placed over a layer of subcutaneous fat that from all appearances was blessed with only a very meager blood supply. Four days later when the dressings were removed the skin was growing nicely and continued to do well. Areas with granulations so exuberant and vascular that they could not be trimmed down because of bleeding were covered satisfactorily. Areas with soupy exudate were covered by thin sections which grew. In general, our aim was to get skin coverage at the earliest possible moment, and the more vigorously this policy was pursued the better were our results both in patient comfort and ultimate function of extremities.

CHEMOTHERAPY

Chemotherapy usually varied directly with the extent and degree of the burn. With first and second degree burns, very little drug of any type was used. Recently these patients have received none and are apparently doing as well as those who received sulfonamides. In the third degree burns nearly all were given either a sulfonamide or penicillin. In the early cases when supplies of penicillin were limited sulfadiazine, 4 to 6 grams daily was given with frequent checks of blood level. Those patients who showed evidence of sepsis were put on penicillin 25 000 units every 3 hours. Usually this was continued for about 10 days while skin grafting in stages was continued. One soldier with over 40 per cent of body surface involved had penicillin for 30 days, 200 000 units daily while skin grafting proceeded. At present we are using penicillin therapy in all extensive third degree burns.

Locally sulfadiazine cream in fine mesh gauze was used as the initial dressing and was continued on subsequent dressings until it was established whether the burned skin was being saved or lost. On donor sites we sprinkled sulfanilamide crystals and covered these with fine mesh gauze and pressure dressings plus immobilization just as for the burned areas.

A stimulating dose of tetanus toxoid was given to all shortly after the injury.

SEPSIS

If and when infection developed in the open wound of a third degree burn the problem was a real one. Particularly was this true in the summer when flies abound. Some patients during transportation could not be adequately protected from flies and at the removal of the initial dressing it was not uncommon to encounter maggots. Once hospitalized at a fixed hospital where the treatment could be carried on without interruption, adequate fly control rigid use of nets sprays and screening when available soon reduced the flies.

The infection of *Bacillus pyocyaneus* with its bluish exudate was frequently present. When the exudate was not profuse it was disregarded and grafting continued. When profuse openings were put into the cast and 0.5 per cent acetic acid in small quantities was used to moisten the dressings once daily with good results.

With mild infections of other invaders sulfanilamide was sprinkled over the wound and sulfadiazine given by mouth. In our recent cases, however we have used only penicillin 25,000 units every 3 hours continuously at the first sign of fever or purulent exudate. Meanwhile skin grafting continued.

When the subcutaneous tissue became involved phlegmonous, and swollen wet dressings of moist, warm boric acid solution were used. Pressure dressings as before were used except that muslin or ace bandage was used for a cover instead of plaster of Paris. Skin grafts under this treatment did not take as well but were continued because the results were still better than 50 per cent successful.

Tub baths were not available.

Sulfadiazine cream strips were not used in the presence of exudate from infection because it was felt that a nongreasy dressing would better absorb the material. Neither was this considered a good dressing over freshly laid grafts because of the possibility of causing the sections to slip.

BLOOD REPLACEMENT

None of the patients with first and second degree burns required transfusions. All had plasma, 1 unit for each 5 per cent of body surface involved.

Nine of the 6 patients with third degree burns required transfusions and a few required additional plasma. In general it can be stated that patients with extensive burns will require blood. Four of our patients required 8 units (500 c.c. each) of blood. Three of these soldiers had 30 per cent body surface involved and the fourth had 40 per cent involvement. However one man with 35 per cent body surface involved required only 1 unit. One soldier with only 10 per cent body surface involved required 2 transfusions but he had considerable infection of a burned forearm. The other soldier getting blood received 1 unit.

Two patients required transfusions because of secondary bleeding after dissecting off extensive eschar. Areas from which the charred skin is removed bleed very little so adequate precaution was not taken to prevent secondary bleeding. Mild pressure controlled the bleeding in both instances and the blood loss was promptly corrected by transfusion.

ANESTHESIA

In none of our patients was anesthesia used at the initial dressing. No débridement was done. Gentle cleansing of debris or street dirt was accomplished rapidly and almost painlessly whenever indicated. Coverage by sulfadiazine strips was done rapidly and the patient became comfortable with morphine, protection of burned surface and immobilization.

However all subsequent dressings were customarily done under pentothal sodium anesthesia. In patients who had only a small area of first and second degree burn, dressings were usually started without anesthesia and usually tolerated well. If much discomfort was experienced anesthesia was promptly used. All patients were premedicated before being taken to the operating room for change of dressing. Usually the period of anesthesia was limited to 1 hour but a few were kept anesthetized for 1½ hours during grafting procedures. Usually patients anesthetized by pentothal sodium early in the day were hungry for lunch by noon, and always by evening they were ready for a full diet. This diet was important in individuals who were being grafted in stages, every fourth day. Pentothal sodium has been our most satisfactory anes-

thetic and was used in over 95 per cent of patients. No patient received over 2 grams at each period of anesthesia.

Three patients had gas oxygen ether anesthesia on one or two occasions when it was planned to do a long extensive grafting procedure with 3 surgeons at work. These periods of anesthesia lasted longer than 90 minutes; there were no complications, yet recovery of appetite and vigor was slow. Usually several days elapsed before the patient would take a full diet. Whether this was due to the anesthesia or the extent of the grafts might be questioned, but on several occasions we have done extensive grafting under pentothal sodium without ill effects. We have felt therefore that for this purpose the intravenous pentothal sodium is the outstanding agent because of lack of delay in inducing anesthesia and the rapidity of recovery of the patient to accept a full diet postoperatively. We used it liberally so that no soldier need dread either the change of dressings or operative procedures.

On several occasions when recipient sites have been small we have used local novocain infiltration for the donor site but usually there were a few granulations on the recipient site to be trimmed down and some discomfort was experienced. As a result we have used local anesthesia only infrequently and only when a few small grafts have been needed.

EXERCISE

The problem of exercise or passive motion is very important in the treatment of third degree burns. In all of our first and second degree burns, bandages were removed and active motion started early enough to prevent any loss of function. Hand and finger motion in second degree burns was encouraged early. Splinting of hands was always with fingers in moderate flexion and thumb opposed. As much of the fingers as possible was left exposed and motion encouraged. When fingers were involved, either active or passive motion was used during the change of dressing.

In the third degree burns, passive motion of all joints in the involved area was exercised during the change of the dressings. Under anesthesia this was not difficult. Casts of extremities were put on with the knee in mild

flexion, elbow in 90 degrees flexion, forearm in neutral position and hand and wrist in position of function with exercise at each dressing or operation.

GENERAL NURSING CARE

The nursing problem on the wards in the present method of treatment is much different from what it was when dressings were done on the wards. All dressings, without exception, were done in the operating room under strict aseptic technique. Therefore the patient arrived on the ward as a package not to be opened. When hands were involved these patients required feeding. Frequent change of position, when possible, was encouraged. Backrubs, bathing of uninvolved areas and general hygienic care are important to these patients. Exercise of burned hands at the earliest possible moment was constantly encouraged by the ward personnel. Plasma and blood as needed were given on the wards. Rigid fly control during the summer season was supervised by the nursing staff. All in all the nursing care of the wards was no more a problem with the burn patients than for an equal number of less severe battle casualties.

Most of our patients never had an opportunity to see their own wounds or those of the other burned patients until the wounds were completely healed or covered by grafting. They were kept comfortable and their morale was good due to the excellent attention of our nursing staff. Numerous letters received from those who have returned to the United States testify to the high regard for the nurses and ward attendants.

In the operating room the change of dressings was done with the usual personnel. Dressings were usually saturated with saline after the removal of casts; the patient was anesthetized and removal of dressings was continued painlessly and easily. None of the patients dreaded going to the operating room—in fact they felt neglected if their procedure was postponed a day longer than usual.

END-RESULTS

There were 2 cases out of the 23 patients with third degree burns of the hands who developed moderate stiffness of the fingers.

Both of these patients were treated early in this series when apparently not enough attention was given to exercise. Both were returned to the United States; one required a plastic procedure and remained in the service. The other reported to us recently that he was separated from the service because of partial disability of the left hand. He secured a job in a war plant and in a letter dated approximately 10 months after his injury he stated that he had recovered almost full use of his hand and was improving. At the present time all of our patients with hands involved are watched carefully and constantly encouraged to preserve hand function. There has been no more than a mild limitation of motion at any of the other joints, all of which should return to full function promptly. In fact, with the exception of the 2 cases mentioned with hand disabilities, all the remaining patients who returned to the United States went because large areas of newly replaced skin could not be expected to function well in the wearing of military equipment or stand the rigors of reconditioning and the trauma of combat. As far as we are able to learn, only the one patient has been separated from service. There were no fatalities.

SUMMARY

In this series of 155 cases no attempt was made to keep a complete record of events for later evaluation; there was neither time nor facility for research. No control group was used—rather as changes in their management were made the previously treated patients became the control group. By the end of this series we concluded that no change need be made in accepted surgical principles. Constant improvement of method and simplification of technique should however be the aim of the doctor who is treating burns.

The treatment of burns lies in the application of surgical principles to the wounds and the wounded. The wounded patient requires comfort, warmth, rest, and supportive therapy. The wound requires cleanliness to

prevent sepsis, gentleness to prevent further trauma, coverage to prevent infection and allay irritation, support and pressure for comfort and to prevent fluid loss, immobilization for comfort and lastly and most important closure of the wound by skin in the shortest possible time to preserve the function of the deeper structures and prevent all the complications that occur in open wounds. The method used to accomplish these requirements is not too important, but any improvement of method that will hasten the accomplishment of recovery and avoid complications is a step forward. We have attempted to improve the method without evading the principle involved.

The treatment of this series of 155 burns represents the work of a group of individuals trained not as experts in the treatment of burns, but a personnel trained in the fundamental principles of management of wounds and wounded soldiers. The results have been gratifying and the following conclusions seem to be indicated.

CONCLUSIONS

- 1 Prompt, clean pressure dressing with immobilization is important in the treatment of burns.
- 2 Prompt administration of a calculated amount of plasma aids in the prevention of shock.
- 3 Infrequent dressing of burn wounds under strict aseptic conditions will help prevent infection.
- 4 Rapid skin replacement is the best method of preventing infection, deformity and dysfunction in the presence of third degree burns.
- 5 Grafts transferred directly to recipient sites adhere well and donor sites do not become infected by working directly between donor and recipient sites.
- 6 Grafts placed immediately after removal of a charred eschar will grow well.
- 7 The use of passive motion under anesthesia will help prevent deformity.

ELECTROLYTIC ABSORPTION OF BONE DUE TO THE USE OF STAINLESS STEELS OF DIFFERENT COMPOSITION FOR INTERNAL FIXATION

J ALBERT KEY M D F A C S., St. Louis Missouri

IN 1941 from a comparative study of stainless steel and vitallium (Key) it was concluded that 18-8 stainless steel and 18-8 S-MO or enduro stainless steel are practically inert in the tissues and are suitable for the internal fixation of bone

It was further noted that the stainless steels mentioned exhibited a slight tendency to corrosion and that some other stainless steel nails which I had used in the past had exhibited considerable localized pitting and one Smith-Peterson nail had corroded into two pieces after over 5 years but had caused no symptoms

It was found that the vitallium nails and plates introduced by Venable and Stuck (4) exhibited even less tendency to corrosion or electrolysis in the tissues and in the solutions used in the experiments than did the stainless steels. But it was believed that the stainless steel possessed certain mechanical advantages which rendered it a more generally useful material for the internal fixation of bone than vitallium. It was stated that the Fracture Committee of the American College of Surgeons should recommend the standardization of 18-8 S-MO or enduro stainless steel for the manufacture of prostheses for the internal fixation of bone and should require such prostheses to be properly labeled in order that surgeons may know what type of stainless steel they are using. The prostheses should be passivated by the manufacturer

The introduction of noncorrosive metals into surgery has led to a considerable increase in the use of internal fixation in bone and joint surgery and a number of new prostheses have been devised. Among those which I have found useful is the Neufeld nail (2). This is a two flanged nail which is bent to form an angle

of about 135 degrees and continued downward as a slightly curved plate. It is useful in the treatment of trochanteric and subtrochanteric fractures of the femur. The two flanged nail is driven into the proximal fragment and the plate is fixed to the distal fragment with three self tapping screws.

The appropriate screws are supplied with the plate and presumably they are of the same type of stainless steel as the plate. In order that corrosion with the attendant absorption of bone from electrolysis and consequent loosening of the screws and plate may not occur they must be of the same type of steel. Unfortunately this is not always true as is shown by the femora illustrated in Figures 1, 2 and 3. Under twilight and local anesthesia these fractures of the femur, 2 trochanteric and 1 subtrochanteric, were reduced by traction and internal rotation on a Bell table and under x ray control the fragments were fixed with Neufeld nails.

The convalescences of the patients whose hips are shown in Figures 1 and 2 were uneventful except that the resorption of bone around the screws and under the plate was so marked that full weight bearing was not permitted until the Neufeld nails and screws had been removed. The cavities in the bones had partially filled in and the bone increased in density to a point where it was believed that unrestricted weight bearing could be practiced with safety. The patient whose hip is illustrated in Figure 2 complained of persistent pain and disability until the nail was removed. It is also my opinion that union of the fragments which was necessary before it was advisable to remove the nails was delayed in all 3 instances. Repeated x rays films of all 3 femora showed progressive absorption of bone around the prostheses, and as this fact was attributed to electrolysis it is believed that

From the Department of Surgery of the Washington University School of Medicine, St. Louis, Missouri.

Fig. 1. Tetrochanteric fracture fixed with Neufeld nail. First operation June 20, 1944. One month after operation not marked electrolytic absorption around the distal screw and beneath the plate of the nail. On the right, the same hip is shown 2 1/4 months after removal of the nail. Note marked regeneration of bone and more firm union of fracture site.

electrolysis was responsible for the delayed union in all 3 cases.

When the plates were removed from the patients whose x rays films are shown in Figures 1 and 2 the screws were found to be corroded and loose. The wire which was used in the subtrochanteric fracture was real 18-8 stainless steel and thus had remained bright and tight. The Neufeld nails were all bright, but they were not tight and the absorption of the femoral cortex which was present beneath the plates is clearly seen in all 3 roentgenograms. The same is true of the absorption of bone around the screws. In Figure 3 a relatively large area of absorption is apparent in the cancellous bone around the proximal and distal screws and union is delayed to such a degree that even now 7 months after insertion of the nail I do not think that it is safe to remove the nail and this patient is still on crutches. In the femora shown in Figures 1 and 2 the absorption of bone around the distal screws is so marked that a pathological fracture through the previously normal bone was a definite possibility. That this was entirely

any other cause is evident from the increased strength of the bone evident in the x ray films which were taken several weeks after the Neufeld nail and screws had been removed. On the basis of these x ray films, unrestricted weight bearing was permitted and the patients seem to be getting along all right. The smallness of the bone in the patient whose x ray film is shown in Figure 2 is due to a partial paralysis of the extremity from old poliomyelitis. The nail in this patient was too long and protrudes into the acetabulum, but this caused no pain or disability. In addition to the absorption of the bone immediately adjacent to the prosthesis, there is some new bone production on the medial aspect of the shaft of the femur in the areas near the points where the screws projected and even in the soft tissues around the projecting screws in Figure 3.

That the danger of electrolytic absorption of bone after internal fixation is not limited to the Neufeld nail is shown in Figure 4. This film illustrates the right hip of a girl, 17 years of age in which the right femur was shortened 2 1/4 inches in order to equalize the length of the lower extremities. An arrest of growth had occurred in the distal epiphysis of the

Fig. 3. Subtrochanteric fracture fixed with Neufeld nail and wire. X ray films taken 5 months after operation. Not marked absorption beneath plate and around distal screws, also new bone formation on medial side of shaft. On right is postoperative x-ray film, few months after operation. Note persistent pain and disability.

opposite femur as a result of an osteomyelitis in early childhood. The postoperative convalescence was uneventful and she left the hospital 17 days after the operation walking on crutches. The hip remained painful but she had no other evidence of infection. In Figure 4 are shown x ray films of the femur 3 months after the insertion of the blade plate and 2 weeks after its removal. The films show marked absorption around the plates and screws and considerable new bone formation. It is interesting to note that the absorption of the dense cortical bone around the two lower screws is proceeding even more rapidly than is that in the cancellous bone. At the second operation the fragments were united the plate and screws were loose and there was no evidence of infection. The convalescence was uneventful and the patient left the hospital on the 14th postoperative day on crutches with instructions to bear a moderate amount of weight on the leg.

Because of the danger of progressive bone absorption from electrolysis Venable (3) has warned against the use of vitallium and stainless steel screws or plates in the same opera-

Fig. 3. Trochanteric fracture 6 months after insertion of Neufeld nail. Union not yet solid. Note marked absorption in the marrow canal around screws and beneath nail, also new bone around projecting screws on inner side of shaft. Still on crutches nail to be removed as soon as union is sufficiently advanced.

Fig. 4. Femoral shortening 3 months after fixation with Blount blade plate and 2 weeks after removal of plate. Note marked absorption especially of cortical bone around the two lower screws also marked new bone formation.

tion or even in the same bone at different operations. The cases illustrated here indicate that the danger of electrolysis perhaps is even greater when different types of stainless steel are used.

Under present conditions it is necessary for the surgeon himself to be responsible for the quality of the prostheses which he uses for the internal fixation of bone. He cannot depend upon the hospital in which he works. Figure 3 illustrates the fact that the correct length of screw is not always available. Only a few days ago while I was applying a bone plate to a tibia it was necessary to stop and check the screws in the Zimmer screw and drill rack. When purchased this rack was filled with an assortment of 18-8 S-MO stainless steel screws of uniform diameter and thread with the standard type of head. When checked on the sterile instrument table, it contained some vitallium screws and 5 different types of stainless steel screws mixed indiscriminately and the $1\frac{3}{8}$ inch screws which were appropriate for the bone in this particular operation were missing entirely their slot and an adjacent slot were filled with screws $1\frac{1}{4}$ inches long.

In addition to the heterogeneous mixture on the rack, there were probably a dozen other types of screws and plates in the operating rooms some of which were purchased in 1912

when the hospital was opened, and this hospital is not unique in this respect. Plates and screws do not deteriorate with age and as new ones are developed, they are purchased and added to the stock, but the old ones are not discarded and they are all mixed together. The average operating room nurse knows nothing of electrolysis and its effect on bone.

In the light of what is known about the deleterious effect on bone of electrolysis caused by the use of metals of different composition for internal fixation it is just as important that the metals used for internal fixation of bone be standardized as it is that drugs be of uniform purity and potency. And, when a prosthesis like the Neufeld nail which is patented and the manufacture of which is controlled is supplied with screws which are of different composition what may we expect of

prostheses which are purchased in the open market and are made by any one of a dozen or more manufacturers?

The surgeon can usually distinguish a vitallium prosthesis from one made of stainless steel unless the former is polished, but he cannot differentiate stainless steels of varying composition at the operating table. It is again suggested that only stainless steel of a uniform composition be used for all prostheses which are to be used for the internal or external skeletal fixation of bone.

A STUDY OF THE VALUE OF LOCAL SULFATHIAZOLE IN OPERATIVE WOUNDS IN THE PROPHYLAXIS OF INFECTION

CHARLES H O DONNELL, M D JOSEPH L POSCH M D Captain M C A US and
JOHN WINSLOW HIRSHFELD M D Detroit, Michigan

THE power of sulfonamides when administered by mouth or by vein to inhibit the growth of certain bacteria in the human body is well established. Although this method of therapy has had spectacular success in the treatment of many infectious diseases such as lobar pneumonia it has not been effective in preventing infection in accidental or surgical wounds. This may be due in part to the fact that many of the bacteria which cause wound infections are not susceptible to sulfonamides in the concentration that can safely be maintained in the body through systemic administration. Since many of these organisms are inhibited *in vitro* by high concentrations of the sulfonamides it seemed logical to place the drugs directly in surgical and traumatic wounds. By this means a greater concentration of sulfonamide could be obtained in the wound than could possibly be achieved by systemic administration. This practice first advocated in 1936 (6 11 13 14 32) has become so popular that many surgeons routinely place sulfonamides in their operative wounds.

Strangely enough in spite of the extensive use of sulfonamides in human wounds for the purpose of preventing infection there is little published evidence to prove that the practice is of value. Many of the workers who have claimed that the local use of sulfonamides decreases the incidence of wound infection either have not employed controls or have compared a sulfonamide-treated series with a control series treated one or more years previously (3 5 12 15 19 20 26 27 29 30). This form

of comparison often leads to fallacious conclusions (22 24) because so many factors which influence the incidence of infection will vary significantly over these long periods. Those authors who have reported controlled series of cases have either reported only a small number of cases (4) or have not been able to confirm the opinion of those who believe that the sulfonamides prevent or decrease the incidence of infection when placed in operative or traumatic wounds (16 23 25 33).

If a substance is recommended for application into wounds the effects of the material on wound healing should be known. Critical evidence in regard to the effect of locally implanted sulfonamides upon wound healing is controversial. Animal experiments have shown that all the sulfonamides when implanted locally may produce an inflammatory reaction and even actual abscesses (34). It has been reported that retarded wound healing and extensive cutaneous scarring is to be expected with the local application of sulfonamides (1 9 35 36). Others concluded that delayed healing is due to excessive amounts of drug locally and stated that when used in proper amount sulfonamides in no way retard healing or result in inefficient scar formation (4 17 18 20 21). After studies on humans it was found that sulfonamides may act as irritants. It was demonstrated however that the deleterious effects are shortlived and that subsequent healing is within normal limits (28).

Because of this conflict of opinion and because of the widespread use of these drugs in wounds we undertook a study of our own to evaluate the use of sulfonamides locally as a means of preventing infection in operative wounds.

The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Wayne University.

From the Department of Surgery, Wayne University College of Medicine, and the Division of Surgery, Detroit Receiving Hospital.

TABLE I.—CLEAN WOUNDS

Bone operations	27
Minor surgical cases	99
Herniorrhaphies	74
Laparotomies	70
Total	270

MATERIALS AND METHODS

Sulfathiazole was selected as the sulfonamide which according to theoretical considerations would be most likely to be effective in preventing infection. Two preparations were employed: sulfathiazole powder and a 20 per cent suspension of microcrystalline sulfathiazole in saline (5 7 8 31). The powder was sterilized before use by dry heat at 140 degrees Centigrade for 1 hour. The microcrystalline form was used as supplied by the manufacturer. All of the wounds were closed without drainage. Sulfathiazole was never packed in a wound but a quantity just sufficient to frost the surfaces was spread evenly throughout the wound just before closure. Care was taken not to place sulfathiazole between the skin edges.

The patients who were all admitted to one of the surgical services at the City of Detroit Receiving Hospital were followed personally by the authors from the time of operation until wound healing was complete. Frequent inspections of the wounds were made; cultures were taken of any exudate; and the condition of the wound was noted and recorded on special summary sheets.

For purposes of study the series of 576 patients was divided into two main groups—patients with clean surgical wounds, and patients with contaminated wounds.

A clean wound was defined as one made deliberately by the surgeon and not contaminated during the operation by a bacteria laden material such as saliva, feces, or pus. The contaminated wounds were either traumatic wounds or operative wounds which were con-

Miscellaneous	1
Total	283

taminated with infectious material during the operative procedure. Only traumatic wounds made with a sharp object and which could be debrided and readily closed without tension were included in the series. Subdivisions were made in each of the groups in order to make the wounds as comparable as possible. Patients in each of the subdivisions were alternated as drug treated or controls.

The subdivisions of the clean wounds were (1) wounds made for open reduction of fractures (2) minor surgical procedures, such as lymph node biopsy (3) wounds made for herniorrhaphies (4) wounds for laparotomies. The subdivisions of the contaminated operative cases were (1) wounds made to repair perforated peptic ulcers (2) wounds made for removal of acutely inflamed appendices (3) wounds made for gastric resection (4) wounds made for operation on the intestine and (5) a miscellaneous group.

About 90 per cent of the operations were performed by 6 surgeons of the resident staff. The skin preparation, type of incision, and suture material were constant for each procedure.

Except for 14 patients who had sulfonamide therapy systemically because of pulmonary complications, none of the patients received any chemotherapy other than sulfathiazole in the wound. None of these 14 patients developed infected wounds.

RESULTS

The distribution of the cases is shown in Tables I and II.

TABLE III.—CLEAN WOUNDS

Drug	No. of cases	Infections	Per cent wound infections
+	28	5	18

TABLE IV.—CONTAMINATED WOUNDS

Drug	No. of cases	Infections	Per cent wound infections
+	26	14	54

Table III compares the incidence of infection in the clean wounds which were treated with sulfathiazole with those which received no drug. Five infections occurred in 128 drug treated patients making an incidence of 3.9 per cent while only 3 occurred in 142 patients who received no drug, an incidence of 2.1 per cent. The incidence of infection in the two groups is almost identical.

A comparison of the contaminated wounds is shown in Table IV. In this series the incidence of infection in the patients who received sulfathiazole is less and it appears as though the drug exerted a beneficial effect. However this difference is not statistically significant (2/10).¹

The wounds in which sulfathiazole had been placed were more indurated than the control wounds and there was a higher incidence of hematoma in the drug treated group. These figures are given in Table V. Wound separation was rare but occurred more often when the drug was not used locally.

Periodic tabulation of the cases and tabulation according to each surgeon demonstrated that the figures given in the tables were consistent throughout the study.

The organisms which caused most of the infections were *Staphylococcus aureus*, alpha beta and gamma hemolytic streptococci and *Escherichia coli* alone or in combinations.

No definite evidence was produced to show that there was any difference in the effect of suspension of microcrystalline sulfathiazole or macrocrystalline powder.

EVALUATION OF STUDY

The statistics obtained from this study are reliable because the control series is comparable with the treated series. By classifying the patients into the various groups there tends to be only one important varying factor—whether or not sulfathiazole was used as local implantation in the wound before closure. There was no selection of cases for use of the drug. These are parallel alternating unselected controls.

Sulfathiazole when used locally in operative wounds just before closure caused an increase

TABLE V—WOUND COMPLICATIONS OTHER THAN INFECTION

Type of case	Drug	N. of cases	Increased induration	Hematoma	Total	Complications per cent
Clean	+	128	0	6	5	3.9
Clean	-	142	7	3		7.0
Contaminated	+	50	6		8	1.5
Contaminated	-	50		3	3	8.6
Total	+	184	13	8	43	5.1
Total	-	202	7	6	23	7.9

in the incidence of wound complications notably increased induration with possibly delayed healing.

In heavily contaminated wounds sulfathiazole used locally seemed to decrease the incidence of infection but did not eliminate it. In clean wounds the incidence was not appreciably affected. The explanation of this divergence may be that in clean wounds there are not many bacteria and the incidence of infection is usually low. Here the foreign body reaction of the drug and its tendency to hematoma formation overshadow its antibacterial effect. In the contaminated wounds there are more bacteria and the natural incidence of infection is higher. Here the antibacterial effect of sulfathiazole is more important than its irritating effect on the wound and it decreases the incidence of infection. This treatment, however, is far from satisfactory as the incidence of wound infection is still 9 per cent. Furthermore applying the principles of statistical methods the difference in percentages of wound infections in the treated and control series even in the contaminated cases is not statistically significant and may be due merely to chance. Accepting this concept we could reconcile the findings in the clean and contaminated series. That is, there is no appreciable change in the incidence of wound infection brought about by using sulfathiazole prophylactically.

CONCLUSIONS

One can conclude from these results that sulfathiazole used locally in wounds does not prevent wound infection. There are several reasons for this conclusion.

¹The statistical significance of the results were checked by Dr. Henry H. Bailey of the department of mathematics, College of Liberal Arts of Wayne University.

1 The organisms which cause wound infection are not very susceptible to the sulfonamides.

2 Dead tissue and foreign bodies which are of necessity present to some extent in any wound, inhibit the action of sulfonamides.

3 Sulfathiazole leads to increased bleeding and hematoma formation a factor known to predispose to infection.

These disadvantages together with their proved inability to prevent wound infection should lead us to seek other means of decreasing the incidence of infection in surgical wounds.

VASOEPIDIDYMAL ANASTOMOSIS BY PRODUCTION OF PERMANENT FISTULA WITH USE OF STAINLESS STEEL WIRE

LEWIS MICHELSON M D., San Francisco, California

AZOOSPERMIA as a cause of sterility in barren marriages is a common finding. Hotchkiss (4) found that 18.6 per cent of the men in his series of 100 in fertile marriages showed no spermatozoa in the semen. In my series of infertile couples 13.3 per cent of the men had no spermatozoa in their semen while in those couples in which the husband was either a contributing or a sole factor of the infertility the incidence of azoospermia was 26 per cent.

(The absence of spermatozoa in the semen may be due either to failure of the testes to produce sperm or to blockage of the efferent ductal systems so that spermatozoa cannot pass into the semen. The etiology of this condition is often obscure. I was unable to determine it in 65 per cent of my cases.)

(The globus minor of the epididymis and the adjacent portion of the vas are the commonest locations for the obstructive type of lesion. Pre-existing localized inflammations probably account for the majority though severe trauma is not an uncommon cause. Bothe and Robinson have described congenital strictures which if bilateral would cause azoospermia.)

Gonorrhea is the specific disease which has most frequently been shown to be a cause of the obstructive lesion. Of course such an infection must usually effect a bilateral blockage of the efferent ducts to produce an azoospermia. However it is well to bear in mind that unilateral blockage can cause the same changes in the semen as that of bilateral lesions, if the opposite testicle is atrophic. Nonfunctioning spermatogenic tissue is a common sequela of cryptorchidism or mumps orchitis and occasionally follows severe trauma to the testis. Unilateral testicular atrophy together with contralateral blockage of the epididymis or vas will result in azoospermia.

It is worthy of note that the gonococcus never attacks the epididymis of an atrophic

testicle. At least the author has not seen this occur nor has any reference to it been noted in the literature.

Remedial therapy of sterility due to blockage of the epididymides or vasa or both, has as its objective the re-establishment of the patency of the ductal passageways and the subsequent liberation of the imprisoned spermatozoa. In 1902 Martin devised an operation to accomplish this end. He united the vas with the epididymis using silver wire sutures thereby establishing an anastomosis of the patent sections of each and bypassed the occluded areas. Hagner (2,3) pursued Martin's technique of vasoepididymal anastomosis and was able to report cures in 58 per cent of the cases in which the anastomosis was performed. Humphrey and Hotchkiss employed fine arterial silk as suture material. Hotchkiss (5) states: "Successful results should reach about 20 per cent of those operated upon and yet the failures are no worse off than prior to operation. Nevertheless most urologists have had so many failures with the Martin-Hagner method that commonly the sterile patient is advised against submitting to any surgical treatment."

Recently the author has devised and performed an operation for vasoepididymal anastomosis which appears to promise better chances for successful results. This operation is a modification of the Hagner-Martin method and introduces a new principle in that a permanent fistula is produced between the lumen of the vas and the globus major of the epididymis. This is accomplished by means of stainless steel wires¹ which are in

¹The use of stainless steel wire as the least irritating foreign material both for sutures and for the production of the fistula, was suggested by Dr. Sterling Bunnell. Hotchkiss (5) suggests that nickel-iron wire may be used for the anastomosing material. He records that Dr. J. H. Draper has demonstrated that either silver or nickel-iron wire may remain in the lumen of the ductus deferens of the dog for months without causing inflammatory reaction or foreign body response.

Fig. 1. The testis, epididymis, and cord have been delivered from the scrotal sac. The vas has been isolated and held up by umbilical tape. In this and the following illustrations the vas and epididymis have been drawn disproportionately large.

sorted into the lumen of the vas through the incision for the anastomosis, passed upward in the lumen and out through its anterior wall then brought out through the skin of the scrotum where the ends are fixed with shot. The lower ends of the wires are passed through the window cut in the globus major for the anastomosis and out the opposite side of this organ. They are then passed through the tunica vaginalis and the skin of the scrotum below the incision and fixed with shot. These wires are removed in 10 to 14 days. The steps of the operation are given in the following description.

Spinal anesthesia is the method of choice.

The scrotum and pubic region are prepared as for any intrascrotal operation. A longitudinal incision 5 to 6 centimeters long is made on the lateral anterior surface of the skin of the scrotum. The underlying layers of the muscle and fascia are incised, the tunica vaginalis is opened and the testis, epididymis, and adjoining portions of the cord including the vas, are delivered (Fig. 1).

The testis and epididymis should be examined for any gross pathology. The vas is isolated and a convenient point is selected for anastomosis with the globus major of the

epididymis. An oblique incision is then made across its anterior wall to expose the lumen. A dilute solution of methylene blue is injected into the terminal segment. A free flow of fluid will indicate that no obstruction exists distal to this point. A slight blockage might be overcome by the introduction of a strand of silkworm gut into the vas, thereby subsequently permitting the fluid to pass by the occluded point. If found obstructed at one site it may be possible to perform the operation at a slightly higher level. Upon establishing proof of patency the incision is then extended longitudinally and its margins are trimmed so that an oval window about 0.5 centimeter long is produced (Fig. 2). Attention is now turned to the epididymis, and an oval opening of approximately the same size is cut out of the lateral superior portion of the globus major of the epididymis (Fig. 3 C). The secretions from the excised tubule are immediately examined microscopically for spermatozoa. It is encouraging to demonstrate them in the epididymis at the point selected for anastomosis but the operation should not be abandoned if none is to be

Fig. 2. A small incision has been made in the vas, and it has been enlarged and made oval in shape. Three wires threaded on blunt ended needle have been passed through the incision, up the lumen of the vas and out through its wall.

Fig. 3. A The group of three wires has been passed through the oval incision in the vas, up the lumen of the vas, and out through its wall. The four wire sutures (1, 3, 3, 4) to make the anastomosis are shown. B Diagrammatic cross section through the vas showing depth of anastomotic suture wires in its wall. C, The oval fenestra has been cut in the globus major. The needle carrying the fistula wires from the vas has partly been passed through the globus major. D The anastomosis between the vas deferens and epididymis has been completed. The three wires which temporarily maintain the fistula are shown. Their course is indicated by the dotted line. The four anastomotic suture wires have been passed and tied. Three of them have not been cut and are shown.

found. This policy is substantiated by precisely such an experience on one occasion. Although a smear from the epididymis was negative a biopsy of the testis secured at the time of operation revealed spermatozoa to be present in the seminiferous tubules and ultimately they appeared in the semen when it was examined after recovery from the operation (Fig 5 a, b).

A blunt nosed straight cambric needle threaded with three stainless steel wires (No 36 20 to 25 cm long) is then passed up the lumen of the vas for a distance of about 2.5 to 3.0 centimeters and then carefully pushed through its wall (Fig 2). The needle is removed

and the wires are threaded on a cutting skin needle. The lower ends of these three fistula producing wires are then threaded on a suitable size Ferguson needle and passed through the window cut in the globus major and out the other side of the epididymis (Fig 3 C). The wires are then threaded on a curved skin needle and left loose. At the margins of the incision in the vas four stainless steel wire sutures (40) are passed through its wall, but not into the lumen (Fig 3 A B). One each at the superior and inferior angle of the incision and one each midway laterally. These sutures are then passed through the tunica vaginalis, and several loops of the epididymal

Fistula wires and shot
to be removed later

Fig. 4. The operative wound in the scrotum has been closed. The mattress sutures are not shown. The ends of the group of the three fistula maintaining wires have been brought out through the scrotal skin and are held in place by shot. These wires are removed to 4 days post-operative.

tubule at corresponding points on edges of the window already cut in the globus major. The inferior and posterior lateral sutures should be approximated and tied first, then the upper and anterior lateral sutures. One or two sutures of catgut fix the vas to the epididymis about 0.5 cm. to 1.0 centimeter below the anastomosis (Fig. 3 D). The testis and other structures are then returned to the scrotum.

The lower ends of the fistula-producing wires which have been threaded on a skin needle are passed through the tunica vaginalis and the skin of the scrotum about 2.0 centimeters below the end of the incision in the scrotum. Similarly the upper ends of these wires are passed about 2.0 centimeters above the upper end of the scrotal incision. The tunica vaginalis is sutured with catgut after first the introduction of an exploring finger to make sure that the organs are in proper position. The incision is closed with deep mattress sutures of silk worm gut and the skin with a running catgut suture. Before the incision is closed it is advisable to measure on the wires where the shot should be applied so that there will be no tension. Following the closure of the skin incision both the lower and upper ends of the wires are shot separately (Fig. 4). Tincture of benzoin com-

Fig. 5. Biopsy of testis. Case of azoospermia, 41 years. a, left, Low power. b, right, High power. Normal testicular tissue. The very small black bodies (tubules) are spermatozoa. Spermatozoa absent in smear from

epididymus 1 time of operation. Active spermatozoa present in ejaculated semen specimens which are taken during postoperative period of 1 to 7 months (last examination).

pound gauze and a large sized suspensory are applied with plenty of gauze for pressure.

The fistula wires are removed in 10 to 14 days without any difficulty. Convalescence in all cases has been uneventful.

The patients have had no serious pain and no complications have occurred. The swelling of the soft tissues remains 3 to 6 weeks. After 3 to 4 weeks the site of the anastomosis can be felt as an indurated mass about 2.5 to 3.0 centimeters in length and about 1.0 centimeter in width. This mass gradually subsides until in from 2 to 4 months it shrinks to a small hard body about 1.5 by 0.6 centimeter. There is very slight tenderness on pressure and the patient experiences very little if any discomfort after the first couple of weeks.

With the exception of this area of anastomosis in all cases the testes, epididymides and vasa appear grossly normal. As there has been no occasion to explore the patients operated upon, no microscopical examination has been possible. In experiments upon dogs the author found no changes in the testes although small fibrotic areas were found in the globus major with fibrotic occlusion of the vas at the anastomotic area.

[This operation has been employed in 5 cases of azoospermia due to blockage of the ductal systems. The gonococcus had been the primary causative agent in 4 cases whereas the fifth was traumatic in origin. Bilateral occlusion was present in 4 while the fifth had unilateral testicular atrophy with occlusion of the epididymis on the opposite side.]

The operation was completed on both sides upon 2 of the men and in the remainder the anastomosis was done on one side only.

Spermatozoa have been found in the semen following operation in 2 of the cases. Atrophy of one testicle precluded the performance of a bilateral anastomosis in one of these patients. There has been one pregnancy.

The types of cases which have failed to demonstrate spermatozoa in the semen are as

follows. The number of weeks postoperative that the semen was last examined is given.

Type 1 Patient suffered from postgonococcal bilateral vasoeepididymitis. Operation was performed November 7, 1944. Bilateral anastomosis was done. Semen was last examined 3 weeks after operation.

Type 2 Patient suffered from postgonococcal bilateral vasoeepididymitis with unilateral complete occlusion of vas. Operation was performed January 30, 1945. Unilateral anastomosis was done. Semen last examined 11 weeks after operation.

Type 3 Patient suffered from post-traumatic bilateral occlusion. Operation was performed October 31, 1944. Unilateral anastomosis was done. Semen was examined 16 weeks after operation. 

Spermatozoa may appear in the semen any time up to the twelfth postoperative month and therefore the procedure cannot be completely evaluated until 1 year has passed.

SUMMARY

Five cases of azoospermia due to blockage of the ducts of the vas and epididymis are herein reported. A new operation is suggested in which stainless steel wires are interposed in the fenestra of the vasoeepididymal anastomosis to further the development of a permanent fistula between these two structures. The series of cases is small but the percentage of successes is comparatively high. With further development of the technique it is hoped that more favorable results may be achieved.

THE TREATMENT OF VARICOSE VEINS

DAVID LYALL, M.D., F.A.C.S. New York, New York

GROWING experience with varicose veins of the legs gives rise to more accurate understanding of this condition and makes possible the expansion and refinement of therapy. The treatment of 200 private patients seen since January 1943, forms the basis of this paper. All the details of diagnosis, treatment, and follow up have been carried out by me. It is my belief that this continuity of supervision tends to give the best results. Most clinics have to overcome the difficulty of insufficient personnel and an ever changing house staff. In addition since their clientele is from the lower income groups the staffs must constantly surmount ignorance, poor hygiene, and lack of co-operation. To a large extent these factors can be discounted in the present study.

Many of these patients present a superficial sameness which not only dulls interest but stifles critical appraisal. One can only say that careful examination and choice of treatment bring gratifying results.

ANATOMICAL

There are three vein systems in the leg (6) (a) the short or external or lesser saphenous, (b) the long or internal or greater saphenous, (c) the femoral or deep circulation. There is also a variable network of superficial veins, particularly about the knee, thigh and buttocks which can become varicose under certain conditions. These varicosities are not always associated with valvular deficiencies; hence, in certain cases, saphenous ligation is not indicated.

PATHOGENESIS

Absence of valves. Studies in cadavers by Eger and Casper showed absence of valves in the external iliac and femoral veins proximal to the orifice of the saphenous in 36.8 per cent of cases. In this series one or both sides were deficient in valves, the left side approximately twice as often as the right. No attempt was made to correlate valve deficiency to the presence of varicosities. The conclusion that on an anatomic basis there is a 36.8 per cent minimal potential incidence of varicose veins of the lower extremities is an interesting hypothesis.

Valve incompetency. Routine tests for valve competency are applicable to any segment of vein one wishes to study. They do not permit distinc-

tion between developmental absence and acquired deficiency. It seems reasonable to assume that normal veins subjected to continued abnormal stress could be dilated to a point where the valves no longer close. This frequently happens in individuals following femoral phlebotomies when the superficial veins serve as dilated collaterals. Once the valve rings are stretched, incompetency increases, even after recanalization of the thrombosed vessels. Occasionally, however, I have found valve incompetency in the perforating veins—blowouts—which disappeared following bedrest and elevation only to return on prolonged unsupported standing. The moral of this is to examine thoroughly for "blowouts" when the patient is first seen. At this time the veins are usually biggest and the maximum number of "blowouts" can be discovered and marked for excision.

Valve incompetency exists most often at the greater saphenofemoral junction—making necessary the classical saphenous ligation. Usually this incompetency exists when the greater saphenous system is varicose. Occasionally the saphenous vein at operation is small and normal in appearance. In such cases there is usually a "blowout" farther down the thigh—sometimes only 2 or 3 inches below the saphenous bulb.

Another frequent point of incompetence is at the orifice of the lesser saphenous vein. This condition may exist by itself or be associated with greater saphenous varices. Incompetent valves in the perforating veins usually do not exist without one of the valvular defects above noted.

Venous pressure in standing individuals is the same in "normal" as in varicose veins (5). It corresponds roughly to the hydrostatic pressure of the blood column leading to the heart. In the recumbent position, in both antecubital and saphenous veins, pressures are elevated in patients with large varicosities. This is probably due to increased blood volume caused by partial emptying of the capacious varicose reservoir. The abnormality is corrected by proper treatment. Orthopnea in patients with mild degrees of heart disease is frequently relieved by proper attention to varicosities.

When the veins are full, as in the erect posture, blood flow in varicosities is upward, although slowly as can be shown by venography. The

Fig. 1. a, Deficient vascular type showing bodily configuration. Note irregular mottled skin. b, Same patient. There are varicosities of the right greater saphenous system. c, On the left side the varicosities arise from a "blowout" in the upper posterior thigh. Neither saphenous system is involved. Note telangiectasia about ankles.

idea that blood flows out of the fossa ovalis and down the saphenous vein is erroneous and implies a pressure differential that does not exist. In normal veins the flow is rapid because of (1) the smaller caliber and (2) muscle action. The latter compresses a vein segment between two valves, blood flows through the upper valve which closes when compression ceases and the segment again fills from below. When valves do not function this progression is not maintained and the blood stagnates (Fig. 2).

Constitutional factors. Empirical observations allow the segregation of some of these patients into groups according to body type. (a) *A deficient vascular group* (Fig. 1). In this group there is extensive superficial venous dilatation manifested by capillary hemangiomas, telangiectases and a multitude of small varicosities. The legs are usually large out of proportion to the rest of the body. Sometimes there is immense adiposity of the buttocks, thighs, and legs suggesting glandular dysfunction. The larger vessels when exposed at operation are thin walled and tremendously dilated. There may be sacular bulges up to 4 or 5 centimeters in diameter. There may be associated hemorrhoids or vulvar varicosities. The overlying skin is irregular and mottled, becoming

easily discolored. I have seen this type more often in females but frequently in males of the Froehlich habitus. Treatment is apt to be prolonged, difficult, and unsatisfactory. (b) *A type apparently deficient in connective tissue* (Fig. 3). This individual is usually male, lean, muscular of athletic type with a long spare build. In him varices appear in early adult life and gradually enlarge through the years. He has little sub-

Fig. 2. a, Normal segment of vein between two competent valves. Upper valve closed, supporting blood column while segment fills from below. b, Normal vein segment. Muscle action compresses segment partially emptying it, lower valve holds it tight. c, Varicose segment. Valves incompetent. Muscle action can force blood in either direction. Upward flow not accelerated.

Fig. 3. a, Type decidant in connective tissue. Long, spare build. Bilateral enlarged external inguinal rings. Small left direct inguinal hernia. Small right varicocele. b, Same patient. Saphenous enlarged from groin to internal malleolus. No other varices. Other leg normal.

cutaneous fat so that all his veins are prominent. He may have an associated varicocele and is subject to inguinal hernia. Telangiectasia and pigmentations are uncommon. Treatment is more easily carried out and results are generally good. (c) *Congenital venous abnormalities*. These enlarged veins may be associated with other stigmas such as extensive hemangiomas. They are characterized by abnormal vascular connections and extensive valve deficiency. I have seen a patient with the entire right lower extremity covered with capillary hemangiomas extending onto the abdomen and buttocks. The enormously dilated right saphenous vein passed over the right fossa ovalis across the pubes and drained into the left femoral through the left fossa ovalis. There were numerous free connections between the abnormal vein and the right femoral vein. This type of varicosity is evident at birth or at a very early age.

DIAGNOSIS

The first step is to decide which venous systems are involved. According to Larson and Smith the lesser saphenous valve was incompetent in 7 per

cent of 491 cases. Obviously if this is the only venous abnormality other ligations are not necessary. A large vein or veins appear in the popliteal space near the flexion crease, and the associated varices involve the calf and ankle. If there is incompetence of the saphenofemoral valve, the greater saphenous vein is usually enlarged and may be palpable throughout its course down the inner aspect of the thigh behind the internal condyle of the femur ending in varices involving the medial and anterior part of the calf and leg. In very stout people it is difficult to locate the veins accurately. If there is doubt on this score, the greater saphenous vein should be ligated as a matter of routine. It may appear that neither vein pattern exists. In this case two situations may be present either (1) there is no incompetence in the connections between the superficial and deep veins, or (2) there are isolated incompetent 'perforators'. In the first instance no ligations are necessary and in the second, routine saphenous ligation is useless. The 'perforator' itself must be located and excised.

The patient to be tested for competence of the saphenofemoral valve rests supine with the leg elevated. Gentle massage in a proximal direction will hasten emptying of the veins. A tourniquet is applied high on the thigh firmly but not tightly enough to obliterate arterial pulsations. The patient then stands immediately. If the entire system of varices remains empty and then begins to fill slowly from below one can assume there are no 'blowouts'. The tourniquet is removed. If the veins then fill rapidly from above incompetence of the saphenofemoral valve is demonstrated. (Note: This down flow of blood ceases when the venous reservoir is filled. The blood then flows slowly upward.)

If during the test described the veins fill rapidly while the tourniquet is in place it is presumed that there is a 'blowout' present. The level of the early influx of blood will give a clue to its location. To locate 'blowouts' Pratt devised the following:

An Ace bandage is applied from the toes to the groin and a tourniquet placed on the thigh above this area. As the bandage is removed, a sudden protrusion of a collection of veins shows the point of incompetence. A second Ace bandage, which may be wrapped from above down, exposes only a small area at a time and is helpful (Fig. 4). This is easily and quickly done. I believe, however that the lower Ace bandage keeps the varices only partly empty, that, as it is unrolled, blood fills the visible portion of vein and that the blood may have come from below and not necessarily via a 'blowout'.

Fig 4. a and b Method of locating multiple blowouts using a tourniquet and two elastic bandages, (after Pratt)

Fig 5. a, The leg has been elevated, thus emptying the veins, and a segment of vein isolated between tourniquets. The segment has remained empty in the erect position indicating an absence of blowouts in this segment. b, Test repeated with tourniquets reapplied lower down. Segment has rapidly filled indicating presence of blowout. Note Veins below lower tourniquet remain empty indicating absence of blowouts.

To locate these 'blowouts' more exactly and to prevent the upward reflux from giving false positive tests for 'blowouts' I make repeated application of the tourniquet at different levels emptying the veins by elevating the leg between each application. The presence of a suspected 'blowout' in any vein segment can be readily detected by using two tourniquets (Fig 5). The vein is emptied and a tourniquet is applied on either side of the suspected site. If the isolated segment fills there is a 'blowout' somewhere between the constrictions. By repeating the procedure shifting the tourniquets the 'blowout' can be accurately located and marked.

Measurements As a routine I measure both legs, selecting arbitrary points of reference. The ankles are measured at their slenderest level, the calves and thighs at a point 15 centimeters below and above the upper margin of the patella, respectively. Accurate comparison can be made later.

Pertkes test This test is based on artificial occlusion of the superficial venous return by a tourniquet placed around the upper thigh. The patient then walks for 5 minutes. If the deep venous circulation is blocked the leg becomes congested swells, and is uncomfortable. This means that the superficial veins, both varicose and normal, are acting as collaterals. In this in-

stance saphenous ligation is deferred until recanalization of the deep veins has occurred.

Tests for arterial disease The dorsalis pedis and posterior tibial arteries are palpated as a routine. If these pulses are full the arterial circulation is considered to be adequate. If palpation is difficult or impossible the arterial circulation may be normal since these vessels may show wide variations in caliber and location. Oscillometric readings are then done as an aid in determining the degree of arterial pulsation. The oscilometer should be used of course, in all cases in which there is a history of claudication abnormally cold extremities or other history suggestive of arterial insufficiency.

Varicoseities due to valve incompetence are treated by surgery even in the presence of advanced arterial insufficiency. Saphenous ligation with eradication of incompetent perforators is carefully done. Sclerosis is never attempted in the presence of arterial disease. Ace bandages are not worn postoperatively but rather all efforts are made to promote vasodilatation during the post-operative state. These measures include use of (1) a thermostatic heat cradle (2) alcohol by mouth (3) other vasodilators such as typhoid vaccine or depropanex, (4) mecholyl iontophoresis, (5) lumbar sympathetic novocain nerve block.

Laboratory data. *Erythrocyte sedimentation rate.* This is a valuable index of phlebotic activity. It should always be done if a history is obtained suggesting deep or superficial thrombophlebitis. Elevation of the rate may cause one to defer operation and certainly contraindicates the use of sclerotics.

Blood count. Certain patients have multiple episodes of thrombosis on the basis of polycythemia. Measures to bring the red cell count to normal should be taken before surgical intervention is undertaken.

X-rays. Venography has given valuable information regarding blood flow in varicose veins but has a limited application. It is valuable in demonstrating deep venous occlusion and may help to estimate some congenital anomalies. At best it serves only to confirm the clinical findings.

TREATMENT

Nonoperative Cases

If no valve deficiency can be demonstrated or inferred, it is useless to interrupt surgically any of the veins, varicose or normal. The cases falling into the nonoperative group show scattered, wandering varicos of the superficial type, usually of medium caliber but frequently in smaller veins and associated with telangiectasia. They are unsightly but rarely cause secondary effects, such as edema or ulceration. The treatment is by injection of a sclerotic. I use sodium morrhuate 5 per cent with benzyl alcohol as a routine and sodium ricinoleate 3½ per cent as an alternative in the rare case which shows sensitivity to the morrhuate. All patients should be given a preliminary test injection of 0.3 cubic centimeter of the sclerosing substance at the first visit. This injection is introduced into one of the varices and usually causes no reaction whatsoever. Very occasionally generalized urticaria results and even asthmatic symptoms develop. This situation should respond to an injection of adrenalin followed by ephedrine orally. I have never seen a true anaphylaxis. In two patients sensitivity developed to the morrhuate compound after a course of injections followed by 4 to 6 weeks rest periods. The injections were discontinued because of mild delayed urticaria. Ethylamineoleate has been tried but its effect seems less predictable and the sclerosis less firm and extensive than that from the morrhuate.

Injection is accomplished with a fine sharp No. 27 hypodermic needle. The patient stands—on a table with hand rails—so that the site of injection is roughly at the surgeon's eye-level. The light should strike the leg tangentially so as to fill

houette the vessel. The syringe is held in one hand so that aspiration can be made when desired without changing the grip. Usually if the syringe is held downward, blood will flow into the solution without aspiration. The other hand serves to steady the tissues during the venopuncture. When one of these varices is excessively large, it must be emptied before injection is made. Too much blood dilutes the sclerosing agent, nullifying its effect. An excessively large clot forms, is painful, unsightly and disappears slowly. To prevent this clot formation the leg is elevated after insertion of the needle and the vein is emptied before injection is begun. Sometimes this maneuver is difficult. When this difficulty arises, the patient lies supine and the veins are distended with the aid of a tourniquet which is removed after insertion of the needle.

From 10 to 20 cubic centimeters of solution are injected, depending on the size of the vein and the individual's reactivity. The latter varies considerably. The site of injection is compressed with alcohol soaked cotton wispas used for sterilization and maintained in position with two 4 or 5 inch strips of adhesive 1 inch wide. The length of vein sclerosed per injection is enhanced by the wearing of an Ace type bandage for 2 or 3 days. The bandaging keeps the sclerotic from "puddling" and spreads it along the vein while preventing influx of new blood. If this type of bandage is objected to a 4 inch square of cotton 1 inch thick applied over the injected area and bandaged into place for 48 to 72 hours may be less unsightly. Injections are usually made at weekly intervals. Sometimes four injections totalling 40 cubic centimeters are made in one sitting and are well tolerated.

Occasionally *palliative treatment* is the only sensible course. Operation is contraindicated sometimes by extreme age and often by other more serious illness. Measures taken include: (1) Ace bandages. These are put on before arising in the morning. For long continued use Ace type bandages, flesh colored, with elastic threads interwoven in 3 or 4 inch widths are most satisfactory. (2) If edema permits periods of elevation during the day and continuously at night are scheduled. (3) If there is a tendency to infection daily hot saline soaks are instituted. Should there be evidence of a fungous dermatitis, warm potassium permanganate soaks 1:5000 are applied, daily at first, then alternately with the saline soaks, and finally at weekly or other intervals sufficient to control the situation. (4) Dressings for ulcerations usually are made with some bland ointment. I have no routine and often one must find the best applica-

tion by trial and error. Frequently, a plain dry dressing is the best, and this is soaked off daily. I have tried the various sulfa ointments, such as Vitamin A and D ointment, chlorophyll ointment and others, and have found nothing for average use better than boric acid ointment. (5) *Weight reduction* in the presence of extreme obesity is important.

Operative Cases
